ABSTRACT

Fibroblast-like synoviocytes (FLSs) are pivotal in inflammation and joint damage of rheumatoid arthritis (RA). They acquire an active and aggressive phenotype, displaying increased migration and invasiveness and contributing to perpetuate synovial inflammation and destruction of cartilage and bone. The main current therapies of RA are focused against inflammatory factors and immune cells; however, a significant percentage of patients do not successfully respond. Combined treatments with drugs that control inflammation and that reverse the pathogenic phenotype of FLS could improve the prognosis of these patients. An unexplored area includes the retinoic acid, the main biologic that control inflammation and that reverse the pathogenic phenotype of FLS could improve the prognosis of these patients. All-trans retinoic acid (ATRA) reduces the rheumatoid arthritis (RA) fibroblast-like synoviocyte migration and invasiveness and down-regulated gene expression of cell motility and migration genes. At supraphysiological doses, many of these effects were overridden or reverted by the concomitant presence of tumor necrosis factor (TNF). In conclusion, these results have demonstrated the therapeutic potential of retinoic acid on RA FLS provided TNF could be counterbalanced, either with high ATRA doses or with TNF inhibitors.

SIGNIFICANCE STATEMENT

All-trans retinoic acid (ATRA) reduced the rheumatoid arthritis (RA) fibroblast-like synoviocyte migration and invasiveness and down-regulated gene expression of cell motility and migration genes. At supraphysiological doses, some of these effects were reverted by tumor necrosis factor. Therefore, ATRA could be an RA drug candidate that would require high doses or combined treatment with anti-inflammatory drugs.

Introduction

Rheumatoid arthritis (RA) is an autoimmune disease characterized by inflammation of the peripheral joints involving synovitis and cartilage and bone degradation (Klareskog et al., 2009; McInnes and Schett, 2011). The resident synovial cells, macrophages and fibroblast-like synoviocytes (FLSs), contribute to the disease pathogenesis in multiple ways. Specifically, FLSs acquire an activated status, leading to secretion of proinflammatory mediators, cytokines, and chemokines together with metalloproteases, cathepsins, and other factors contributing to cartilage and bone erosion. In addition, RA FLS acquires some features of transformed cells that are described as unregulated proliferation, resistance to apoptosis, and insensitivity to contact inhibition. These characteristics contribute to cartilage and bone damage by the invasion of the hyperplasic and aggressive synovia. This is a stable phenotype maintained by epigenetic marks and somatic mutations that seems critical for disease persistence and that differentiates RA FLS from healthy FLS (Bartok and Firestein, 2010; Neumann et al., 2010; Ospelt, 2017). Preclinical models have shown the effectiveness of targeting RA FLS, though none of the tested drugs have yet reached clinical use. In contrast, available drugs target the immune and inflammatory

components of RA, but as monotherapy often they are insufficient to achieve remission or adequate control of the disease activity (Smolen et al., 2017). This circumstance has motivated the common use of drug combinations, with the most frequent including methotrexate together with a targeted biologic drug as one of the monoclonal anti–tumor necrosis factor (TNF) antibodies (Smolen et al., 2017). A sizable fraction of patients does not reach adequate response even with these drug combinations. Therefore, there is a growing interest in developing treatments aimed to revert the activated phenotype of RA FLS (Niedermeier et al., 2010). Recently, we found that a transporter of retinoids, cellular retinoic acid binding protein 2, is a candidate drug target of this type because cellular retinoic acid binding protein 2 suppression reverts RA FLS resistance to apoptosis (Mosquera et al., 2018). In the same study, we observed unconventional responses of RA FLS to the main biologic retinoid, all-trans retinoic acid. These results prompted us to investigate further the effects of all-trans retinoic acid (ATRA) on the activated phenotype of RA FLS (Mosquera et al., 2018).

Vitamin A and retinoids are generic designations for an array of essential organic molecules that include retinal, retinol, and retinoic acid. They are needed for the visual system, cell homeostasis and differentiation, integrity of epithelia, erythropoiesis, reproduction, lymph node morphogenesis, response to infection, and other immune functions (Al Tanoury et al., 2013; Coyle et al., 2013). Some retinoids have been used since long ago to treat psoriasis, in which they act on keratinocyte differentiation and proliferation and on the balance between different cluster of differentiation 4 subsets (Brown and Noelle, 2015). In addition, retinoids have been considered for the treatment of several types of cancer and autoimmune diseases. In cancer cells, retinoids induce differentiation, cell cycle arrest, apoptosis, and inhibition of cell migration and invasiveness (Flamini et al., 2014; Young et al., 2015; Cui et al., 2016; Li et al., 2017). In autoimmune diseases, retinoids have shown improvement of animal models of multiple sclerosis (Massacesi et al., 1991), systemic lupus erythematosus (Perez de Lema et al., 2004), type 1 diabetes (Wang et al., 2016), and RA (Kuwabara et al., 1996; Kwok et al., 2012). However, progress to further development of retinoids as new drugs for these diseases has been slow. In the case of RA animal models, some studies have shown disease aggravation in place of improvement (Trentham and Brinkerhoff, 1982, Beehler et al., 2003). The current study was started to explore the effects of ATRA on the key features of the RA FLS phenotype, namely cell migration and invasion. Given that TNF is one of the most relevant cytokines in RA pathogenesis, as supported by the efficacy of anti-TNF treatments, the experiments also involved analysis of the potential influence of TNF on the results.

The principal result of this work has been the discovery of selective modulation by ATRA of several aspects of the RA FLS phenotype. This regulation produces beneficial effects, such as decreased migration and invasion. However, ATRA effects on RA FLS were in many instances overridden or reverted by the concomitant presence of TNF. The TNF over-turning of ATRA effects was observed at supraphysiological doses of ATRA, but a decreased migration could be restated by further increasing the ATRA dose. This need for counterbalancing TNF modulation should inform the design of treatment trials of ATRA and further studies of its role in RA pathogenesis.
were extracted with the Agilent Feature Extraction software and normalized with the GeneSpring GX 13.0 software (Agilent). However, no comparisons of expression data were done at the individual gene level. In its place, a gene set functional analysis was performed. It was based in the rank product order of gene expression, which was provided as the preranked input for the Gene Set Enrichment Analysis (GSEA) algorithm. We used the Hallmark gene sets of the Molecular Signatures Database, which summarize and represent specific well-defined biologic states or processes and display coherent expression. The names of the gene sets do not fully represent their content, which is available at http://software.broadinstitute.org/gsea/msigdb/genesets.jsp?collection=H. A gene set was considered significantly enriched if its normalized enrichment score (NES) ≥3 [all of them showed family-wise error rate (< 10^{-4})]. GSEA and Molecular Signatures Database have been developed and are maintained at the Broad Institute of the Massachusetts Institute of Technology (http://www.broad.mit.edu/gsea/).

Real-Time Quantitative Polymerase Chain Reaction. Real-time quantitative polymerase chain reaction (PCR) was performed in a Rotor-Gene (Corbett Research, Australia), using 1-Step QRT-PCR Brilliant III SYBR Green (Agilent Technologies), according to the manufacturer’s protocol. Relative levels of gene expression were normalized to the TATA-box-binding protein (TBP) gene using the comparative Ct method, in which Ct is the cycle at which the amplification is initially detected. The relative amount of mRNA was calculated according to the 2^{(\Delta \Delta Ct)} method, wherein: \( \Delta Ct = Ct_{target} - Ct_{TBP} \) and \( \Delta \Delta Ct = \Delta Ct_{target} - \Delta Ct_{TBP} \) (Barber et al., 2006). In this way, \( \Delta \Delta Ct = 0 \) and \( 2^{\Delta \Delta Ct} = 1 \) for RA FLS incubated with DMSO 0.05%. For the experimental treatments, the value \( 2^{\Delta \Delta Ct} \) indicates gene expression relative to TBP and the value \( 2^{\Delta \Delta Ct} \) indicates fold change in gene expression relative to the control. The primers were obtained for PrimerBank (Table 1) and manufactured by Sigma-Aldrich.

Data Availability. Data from microarray study have been deposited in National Center for Biotechnology Information’s Gene Expression Omnibus and are accessible through the GEO Series accession number [GEO: GSE120785]. To review go to: https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE120785. Enter token ilitwayybqjfyxz into the box.

The rest of the data generated during this study is available upon request from the authors.

Statistical Analysis. Differences between experimental groups were assessed with the Mann-Whitney U test or the Wilcoxon matched-pairs test. A value of \( P < 0.05 \) was considered significant. Analyses were performed with GraphPad Prism version 5.00 for Windows (GraphPad Software, San Diego, CA).

Results

ATRA Reduces Migration and Invasiveness of RA FLS. We have analyzed whether the treatment with ATRA could have induced the migration ability of RA FLS using a cell wound-healing assay. We used the dose of 5 \( \mu M \) ATRA based on previous literature (Chen and Stallings, 2007; Das et al., 2010, 2013; Foley et al., 2011; García-Regalado et al., 2013) and our previous work (Mosquera et al., 2018). When the FLS cells were cultured with ATRA, the healed area was reduced to about half the control at 96 hours (\( P < 0.01 \), Fig. 1, A and B). In contrast, the cell wound-healing assay in the presence of TNF showed increased RA FLS migration, and this increase was not overcome by the addition of ATRA in the ATRA+TNF assays (Fig. 1, A and B).

In a second step, we tested whether the reduction of migration with ATRA correlated with similar changes in FLS invasion. For these experiments, invasion through an extracellular matrix mimic, Matrigel, was used. The average result of FLS from nine patients with RA showed a significantly reduced number of invading cells (30% fewer FLS) with 5 \( \mu M \) ATRA compared with the control (Fig. 2, \( P < 0.05 \)). This decrease in invasiveness was similar to that observed in the presence of TNF and not significantly different to that found in the presence of ATRA+TNF (Fig. 2, A and B).

Identification of ATRA and ATRA+TNF Regulated Gene Sets by Microarray Analysis. In an attempt to discover clues explaining the previous results at the molecular level, a microarray study was performed. It included one-color microarrays containing about 60,000 probes that were hybridized with cDNA from FLS cultured in four conditions: control medium, ATRA, TNF, and ATRA+TNF. Two pools, including FLS from three different patients with RA each, were prepared with the RNAs and hybridized with the array. The results were used to screen for gene sets that were specifically modified by ATRA (either in the comparison of ATRA with the control or in the comparison of ATRA+TNF vs. TNF) or by the interaction between ATRA and TNF (showing differential effects with ATRA+TNF compared with that observed either with ATRA or with TNF).

Some gene sets showed evidence of interaction between ATRA and TNF effects leading to differential modulation of expression (Fig. 3). Two of them pertaining to interferon gamma response and interferon alpha response were enriched in genes up-regulated by TNF, ATRA, or ATRA+TNF relative to their paired condition except in the ATRA+TNF versus TNF comparison, wherein ATRA+TNF was associated with lower expression than TNF (Fig. 3). Another gene set showing evidence of interaction between ATRA and TNF concerned the epithelial-mesenchymal transition. The genes in this set were down-regulated by ATRA compared with the control, but up-regulated by ATRA+TNF in relation with ATRA. This latter result was observed in spite of the absence of a significant effect of TNF on its own (Fig. 3). Some of the

TABLE 1
Primer sets used for quantitative PCR study
most down-regulated extracellular matrix genes by ATRA were collagen (COL) 5A3, lumican, elastin, tenasin C, COL6A3, COL8A2, COL1A2, and other collagen genes. Six other gene sets showed an enhancement of expression with the combined treatment (Fig. 3). The clearest pattern in this category corresponded to oxidative phosphorylation, which was up-regulated in all ATRA + TNF comparisons without experiencing a significant increase in the wells cultured separately with TNF or with ATRA. A similar pattern was found for the mitotic spindle, DNA repair, adipogenesis, mechanistic target of rapamycin complex 1 signaling, and cholesterol homeostasis gene sets (Fig. 3).

There were four other gene sets showing up-regulated expression associated with ATRA. For three of them, the increase was uniform in all comparisons, indicating that they were stimulated by both ATRA and TNF and further increased by the combination of ATRA + TNF. These three sets are denominated as such: E2F targets, G2M checkpoint, and MYC targets v1. The other set that showed a similar, though less consistent, pattern was TNF-α signaling via Nuclear factor kappa light chain enhancer of activated B cells (NFκB) (Fig. 3).

The remaining gene sets showing significant enrichment were exclusively related to induction by TNF and, therefore, of less interest in the current study. However, it is worth noting to signal their substantial number, 12, and that 11 of them were enriched in up-regulated genes. This bias toward increased gene transcription and the identity of the enhanced gene sets reflected the known effect of TNF in the immune response (Fig. 3).

For the confirmatory experiments, we selected the genes from the first decile of the most significantly enriched pathways (inflammatory response, interferon gamma response, TNF-α signaling via NFκB, and epithelial-mesenchymal transition) that were of interest in cell migration, invasion, motility, or inflammation (Table 2). Some of the 11 genes fulfilling this selection appeared in several pathways, and they were validated by real-time PCR.

**Analysis of ATRA and TNF in the Regulation of Specific Genes.** Real-time PCR of the 11 selected genes was done with FLS from five to seven patients with RA. The commonest effect of ATRA was to down-regulate gene expression. The decrease was significant for epithelial stromal interaction 1 (EPSTI1), matrix metalloprotease 1 (MMP1), C-X3-C motif chemokine ligand 1 (CXL1), pentraxin 3 (PTX3), and vascular cell adhesion protein 1 (VCAM1) (Fig. 4). However, ATRA also down-regulated C-X-C motif chemokine ligand 9 (CXCL9), C-X-C motif chemokine ligand 3 (CXL3), and ST3 beta-galactoside alpha-2, 3-sialyltransferase 5 (ST3GAL5) did not demonstrate differences in the ATRA versus control comparison and that nidogen 2 (NID2) showed up-regulation with ATRA alone. However, ATRA only reverted the TNF-induced expression to the control level for MMP1 (Fig. 4). The inability of ATRA to revert TNF effects was equally apparent in the two genes that were down-regulated by TNF, NID2, and ST3GAL5. These
two genes were further down-regulated by the ATRA+TNF treatment in comparison with the treatment with TNF alone. This potentiated down-regulation was particularly striking for NID2 because the NID2 expression was induced by ATRA in the absence of TNF (Fig. 4).

The two remaining genes, NOD2 and IL1B were not down-regulated by ATRA in any experimental setting but for different reasons. NOD2 expression showed a complete insensitivity to ATRA (Fig. 4). In contrast, expression of IL1B was induced by ATRA, both alone and in the TNF+ATRA combination (Fig. 4).

Dose-Effect Curve of ATRA on the TNF-Induced Migration of RA FLS. To analyze how the interplay between ATRA and TNF affects RA FLS migration at different relative concentrations, we varied the doses of ATRA while keeping the dose of TNF constant (Fig. 5). These experiments showed that ATRA in isolation was able to decrease RA FLS migration even at the lower dose assayed, which was one-tenth of that previously used, with further decrease at higher doses. In contrast, the increase in migration observed in the presence of TNF was not significantly modified with the addition of ATRA in the 0.5–10 μM range. However, higher doses of ATRA were able to significantly overcome the TNF potentiation (0.04 and 0.03 with 20 and 40 μM, respectively). Specifically, the TNF-induced migration of RA FLS was reduced by 35.6% with 40 μM ATRA (Fig. 5).

Discussion

Our experiments have identified new areas in which ATRA could control the FLS-activated phenotype. They include a decrease in FLS migration and invasion, which, when uncontrolled, are pivotal contributors to cartilage and bone damage of the inflamed joints. In addition, ATRA showed down-regulatory effect on the expression of specific genes related to cell motility. However, it did not oppose all aspects of the FLS-activated pattern of expression. This complexity of actions was compounded by the strong effect of TNF, which showed a dominant effect on many of the aspects of the RA FLS phenotype. These results integrate appropriately with the growing evidence indicating the contextual dependency of retinoid actions. Interestingly, we also observed that TNF has opposed effects on the migration and invasion of RA FLS. The cause of this discrepancy is unknown. However, it is necessary to note that concordant increased cell migration and invasion is characteristic of metastatic cancer cells not of tissue growth, inflammation, or wound repair, in which cell motility is increased without invasiveness (Wu and Zhou, 2010; Hulikower and Herber, 2011). In RA animal models, synovial invasion and attachment to cartilage and bone and even transmigration to other joints are present, but TNF is not able on its own to promote them. The experiments in Human Tumor Necrosis Factor (hTNF) transgenic mice show that these processes are dependent on the presence of IL-1 or cartilage damage (Korb-Pap et al., 2012; Hillen et al., 2017; Ospelt, 2017).

No previous study has analyzed the role of ATRA, or any other retinoid, in the RA FLS except for our previous work that was restricted to FLS proliferation and survival. FLSs’ proliferation was insensitive to ATRA, whereas their resistance to apoptosis was exacerbated (Mosquera et al., 2018). The inhibitory effects of ATRA on FLS migration and invasion observed in the current study were in concordance with that found in cancerous and nonmalignant cells.

JAK STAT, Janus kinase signal transducer and activator of transcription.
The reduced migration and invasion of cancer cell lines induced by retinoids correlate in animal models with decreased tumor growth and metastases (Tabata et al., 2009; Zhao et al., 2009; Benelli et al., 2010; Applegate and Lane, 2015; Waters et al., 2015; Williams et al., 2018). These effects together with other beneficial actions have motivated the use of retinoids for the treatment of several malignancies, including acute promyelocytic leukemia (Cicconi et al., 2018; Longfelder et al., 2018), head and neck squamous cell carcinoma (Bhatia et al., 2017), and neuroblastoma (Cheung, 2015).

Gene-set analysis of the microarray data identified a single ATRA down-regulated gene set: the epithelial-mesenchymal transition, which is critical in the RA FLS phenotype (Steenvoorden et al., 2006; Ekwall et al., 2011; Li et al., 2013; Choi et al., 2017). In effect, the FLSs from healthy subjects show some typical markers and functional features of epithelial cells in spite of their mesenchymal origin. These epithelial features are lost more or less completely in the early phases of RA in a process that resembles the epithelial-mesenchymal transition and that includes enhanced migration and active invasiveness. In addition, the epithelial-mesenchymal transition pathway has been identified as the most up-regulated pathway associated with RA FLS invasiveness in a previous transcriptomic study (You et al., 2014). Therefore, down-regulation of the epithelial-mesenchymal transition by ATRA could explain the inhibition of migration and invasion we have observed.

Additional genes that could be involved in migration inhibition were suggested by quantitative PCR results. They showed a marked down-regulation with ATRA of CX3CL1 and EPST11 together with decreases of MMP1, PTX3, and VCAM1, which are included in the epithelial-mesenchymal transition gene set. All these genes are involved in cell migration and invasion (Li et al., 2014; Tan et al., 2016; Tung et al., 2016; Bernardini et al., 2017; Wang et al., 2017; Kong et al., 2018). In effect, VCAM1 participates in the transendothelial migration of leukocytes (Kong et al., 2018), whereas EPST11 (Li et al., 2014; Tan et al., 2016) and PTX3 (Tung et al., 2016; Chan et al., 2017) contribute to cancer invasion and metastasis. Even more relevant is down-regulation of CX3CL1 and MMP1, because they participate in RA FLS migration. On one side, CX3CL1 is a chemokine ligand that induces FLS proliferation, migration, and pannus formation in an autocrine way (Bernardini et al., 2017), whereas MMP1 contributes to migration and invasion as an extracellular matrix protease (Huang et al., 2017; Wang et al., 2017).

Another relevant aspect of our results is the modulation of ATRA actions by the presence of TNF. Its most notable manifestation was the reversal of its inhibition of RA FLS migration. The nature of this modulation is not known, but it was possible to reverse it with larger concentrations of ATRA. In addition, 5 μM ATRA in combination with TNF modulated the gene expression differently than ATRA alone. Many interaction types were observed in our analysis, from potentiation of the TNF effect to its reversal. Then, in further studies it would be interesting to more thoroughly analyze the effect of TNF + ATRA in these pathways.

The interaction of ATRA and TNF has been previously observed in chondrocytes (Huang et al., 2017) and the T helper subset differentiation (Basu et al., 2015; Brown and Noelle, 2015). However, no previous evidence of interaction was available in RA or healthy FLSs or in any other fibroblasts. In addition, epidemiologic studies have found a paradoxical disparity attributed to the contextual dependency of the retinoid effect. So, high plasma levels of retinoids are associated with decreased frequency of some chronic diseases (Rubin et al., 2017; Totti et al., 2018). In RA, low levels of retinoids in
plasma are associated with increased prevalence (Comstock et al., 1997), whereas treatment with retinoids of arthritis models has resulted in a variety of results, from an increase in disease severity (Trentham and Brinckerhoff, 1982; Beechler et al., 2003) to its attenuation (Kuwabara et al., 1996; Kwok et al., 2012).

The beneficial effect of ATRA was observed at the supra-physiological dose of 5 μM, which has been frequently used in in vitro studies (Chen and Stallings, 2007; Das et al., 2010, 2013; Foley et al., 2011; Garcia-Regalado et al., 2013; Mosquera et al., 2018) and broadly corresponds to the ATRA concentrations attainable with the doses used to markedly suppress collagen-induced arthritis in DBA mice (Kwok et al., 2012). In effect, the 0.5 mg/kg of ATRA given to these mice leads to peak ATRA concentrations between 0.6 and 3 μM in serum and tissues, as estimated from the available data in mice (Jing et al., 2017). These concentrations are about 1000 times larger than the endogenous concentration found in the plasma of human subjects (Jing et al., 2017), but there is no reason to expect that they will be associated with intolerable adverse effects because they are about one-hundredth the concentrations found in plasma with the recommended dose for the treatment of acute promyelocytic leukemia (Castaigne et al., 1993; Sanz et al., 2009; Osman et al., 2018). Therefore, the 5 μM concentration was clearly larger than the endogenous ATRA, sufficient for eliciting significant effects in preclinical arthritis models, and likely to be well tolerated.

The dominance of TNF over ATRA on RA FLS reinforces the need for complementary approaches when considering drugs aimed to control the RA FLS phenotype. This idea is widely accepted (Niedermeier et al., 2010). The experience of drugs intended to reduce synovial hyperplasia, including radiotherapy (UPV/EHU) and European funding [European Regional Development Fund (ERDF) and European Social Fund (ESF)].

The possibility that ATRA could be used for the treatment of RA has been pursued only in preclinical studies, as already mentioned (Kuwabara et al., 1996; Kwok et al., 2012). However, the clinical experience of combining treatments in RA is extensive. Current recommendations include the com-
bination of a nontargeted drug, such as methotrexate, with a targeted drug, such as an anti-TNF monoclonal antibody, to treat the patients that show inadequate response (Smolen et al., 2011). The significant fraction of patients that still do not respond has motivated the search for other combinations. Thereafter, a combination of drugs targeting inflammation and the synoviocytes will follow in this tradition.

Overall, the data shown here have demonstrated for the first time that ATRA can modulate the aggressive phenotype of FLS from patients with RA. On practical grounds, it seems reasonable to consider that combined treatments will include drugs to control inflammation and autoimmunity in addition to the RA FLS–directed drug. Therefore, future preclinical trials should consider the many effects of retinoids, including the effects on FLS, the interactions with TNF, and other contextual influences. It is possible that in this way, the effect of retinoids on arthritis models could be clarified and the path to clinical trials could be open in the context of drug repositioning.
