ABSTRACT

The changes in porosity caused by mineral dissolution/precipitation and the associated changes in flow, transport and chemical parameters of porous and fractured media are relevant for the geochemical time-evolution of natural and engineered underground systems. The realistic representation of natural systems requires modeling tools accounting for the changes in porosity. Here, we investigate the significance of the dynamic upgrade of the flow, transport and chemical parameters in reactive transport models with mineral dissolution/precipitation. The water flow, heat transfer and multicomponent reactive solute transport code, CORE^{2D}V5, was extended to take into account the changes in porosity provoked by mineral dissolution/precipitation and their effect on flow, solute transport and chemical parameters. The improvements implemented in the code were verified against analytical solutions and the numerical solutions computed with other reactive transport codes with similar capabilities for isothermal mineral dissolution/precipitation test cases. Model results computed with CORE^{2D}V5 agree with the analytical and numerical solutions for several isothermal test cases with porosity feedback. Model results show that failing to account for the porosity feedback leads to large errors. The porosity feedback effect (PFE) is

23 especially relevant in long-term problems with mineral dissolution/precipitation leading to strong

24 changes in porosity. The PFE is analyzed with a non-isothermal geochemically-reactive transport

25 model of the long-term ($4 \cdot 10^4$ years) interactions of compacted bentonite with corrosion products

26 and concrete in a high-level radioactive waste repository in clay. The model predicts pore

27 clogging in the concrete and at the concrete-clay interface. The thickness of the zone affected by

28 pore clogging computed with the PFE is smaller than that computed without the PFE.

30 radioactive waste disposal, non-isothermal

31 ## 1. Introduction

32 Groundwater flow, heat transfer, and reactive solute transport models are useful tools for

33 understanding natural groundwater bodies, quantifying groundwater pollution and evaluating the

34 performance of waste disposal facilities (Steefel et al., 2005). Reactive transport models have

35 been used within the following realms: 1) Geothermal systems (Alt-Epping et al., 2013a, 2013b;

36 Wanner et al., 2014, 2017; Diamond and Alt-Epping, 2014; Xu et al., 2016), 2) Geological

37 radioactive waste disposal (Yllera et al., 2004; De Windt et al., 2004; Molinero et al., 2004; De

38 Windt et al., 2007; Samper et al., 2008, 2016; Soler et al., 2008; Zhang et al., 2008; Lu et al.,

39 2011; Zheng et al., 2010, 2011, 2017; Berner et al., 2013; Kosakowski and Berner, 2013; Mon et

40 al., 2017; Samper et al., 2018), 3) Geological carbon dioxide storage (Bildstein et al., 2010; Yang

41 et al., 2011, 2014; Wei et al., 2015; Dai et al, 2016, 2018; Todaka and Xu, 2017) and 4)

42 Environmental remediation (Samper and Yang, 2006; Yang et al., 2008; Jamieson-Hanes et al.,

43 2012; Wanner et al., 2012; Wanner and Sonnenthal, 2013; Yeh et al., 2013).

44 Modern reactive transport codes are able to consider a wide range of equilibrium and kinetically

45 controlled biogeochemical reactions, such as: 1) Homogeneous reactions (aqueous complexation,

46 acid-base and redox reactions), 2) Mineral dissolution and precipitation reactions, 3) Multisite

47 surface complexation, 4) Multisite ion exchange reactions, 5) Gas–aqueous phase exchange, and

48   6) Microbial reactions. Steefel et al. (2015) described the mathematical and numerical

49   formulations used in numerical reactive transport codes that consider continuum representations

50   of flow, transport and reactions in porous media. This approach uses a macroscopic scale by

51   averaging system properties. Experimental data are essential to reduce the uncertainties in the

52   parameters and geochemical processes of continuum-scale reactive transport models (Katz et al.,

53   2011; Fox et al., 2015; Poonoosamy et al., 2015, 2016, Shafizadeh et al., 2020). The solution of

54   the inverse problem of multicomponent reactive solute transport provides a way to determine

55   unknown flow and transport parameters by using experimental data (Samper et al., 2006; Dai et

56   al., 2009, 2012; Wolfsberg et al., 2018). However, the continuum approach is not valid to study

57   geochemical reactions and the processes controlling the evolution of porous media that occur at

58   the pore scale. In recent years, significant progress has been made in pore scale investigations

59   (Molins 2015; Seigneur et al., 2017; Deng et al., 2018). Nevertheless, it is not yet feasible to

60   simulate reactive transport on larger scales (m - km) by using pore scale approaches.

61   Numerical simulations of systems in which the dissolution/precipitation of minerals may lead to

62   significant changes in the porosity are complex because the changes in porosity can modify the

63   fluid flow and influence transport and chemical reaction parameters (Chagneau et al, 2015; Min

64   et al., 2016). The porosity feedback effect under isothermal conditions is accounted for in

65   computer codes such as HYTEC (van der Lee et al., 2003), TOUGHREACT (Xu et al., 2004,

66   2006, 2011), HYDRUS1D-PHREEQC (Simunek et al. 2008, 2009), MIN3P (Mayer et al., 2002),

67   PHAST (Parkhurst et al., 2002), CRUNCH (Steefel, 2001) and PFlotran (Hammond et al., 2014;

68   Lichtner et al., 2018). The implementations of the porosity feedback in the reactive transport

69   codes is commonly verified by comparing numerical results with analytical solutions. However,

70   only a few analytical solutions for the porosity feedback effect (PFE) are available in the literature

71   (Lagneau and van der Lee, 2010; Hayek et al., 2011; 2012). Code verification is possible by

72   comparing model results computed with several codes for appropriate benchmark cases (Xie et

73   al., 2015; Poonoosamy et al., 2018). Chen and Liu (2002) developed a method to solve a set of

74   nonlinear equations coupled with fluid flow, species transport and rock/fluid reactions including

75   the alteration of porosity and permeability due to mineral-fluid reactions. Shao et al. (2013) used

76   a numerical model to study the geochemical iterations and the induced changes in the porosity

77   (clogging) in the Maqarin marl rock (Jordan). Seigneur et al. (2018) developed an algorithm to

78   couple accurately the feedback of chemistry on water consumption, variable porosity and flow in

79   variably-saturated reactive transport models. Seigneur et al. (2019) reviewed equations of

80   multiphase flow and reactive transport on the continuum scale, the recent studies carried out on

81   the pore scale and provided a summary of the more common approaches used to describe evolving

82   flow and transport parameters due to mineral dissolution/precipitation reactions in reactive

83   transport models.

84   The CORE series of reactive transport codes have been developed at the University of A Coruña

85   since 1991. CORE^{2D}V4 (Samper et al., 2009; 2011) is one of these codes for transient saturated

86   and unsaturated water flow, heat transport and multicomponent reactive solute transport under

87   both local chemical equilibrium and kinetic conditions. The flow and transport equations are

88   solved with Galerkin finite elements and an Euler scheme for time discretization. The chemical

89   formulation is based on the ion association theory while the extended version of Debye-Hückel

90   equation (B-dot) is used to calculate the activity coefficients of aqueous species. CORE^{2D}V4 uses

91   the EQ3/6 "*com*" thermodynamic database (Wolery, 1992). The codes of the CORE series have

92   been widely used to simulate geological radioactive waste disposal facilities that envisage several

93   engineered barriers such as a metallic canister and a compacted bentonite barrier. Mon et al.

94   (2017) presented a non-isothermal reactive transport model to simulate the long-term evolution

95   of a geological repository in clay and quantify the interactions at the interfaces of compacted

96   bentonite, canister and concrete. This model was calculated with CORE^{2D}V4 by assuming a

97   constant porosity. Failing to account for the changes in porosity, ϕ, may lead to unrealistic results

98   with porosities out of the feasible interval ($0 < \phi < 1$).

99   Here we investigate the significance of the dynamic update of the flow, transport and chemical

100   parameters in reactive transport models with mineral dissolution/precipitation. CORE[2D]V5 has

101   been developed from CORE[2D]V4 to take into account the PFE due to mineral

102   dissolution/precipitation under isothermal and non-isothermal conditions. CORE[2D]V5 has been

103   verified with one- and two-dimensional analytical solutions (Hayek et al., 2011; 2012). In

104   addition, numerical solutions obtained with the two versions of the code CORE[2D] with and

105   without the PFE have been compared with analytical solutions to illustrate the significance of the

106   PFE in reactive transport models with mineral dissolution/precipitation. The benchmark proposed

107   by Xie et al. (2015) has also been used to verify the code against other reactive transport codes.

108   Furthermore, the capabilities of CORE[2D]V5 have been used to evaluate the importance of the PFE

109   on the long-term geochemical evolution of a radioactive waste repository in clay by using the

110   reactive transport model of Mon et al. (2017), which has been extended to account for the PFE.

111   To the best of our knowledge, this is the first time that the importance of the PFE is studied for

112   radioactive waste disposal under non-isothermal conditions. The paper presents first the

113   mathematical formulation of the non-isothermal reactive transport and the dynamic update of the

114   permeability, the diffusion coefficient and the specific mineral surface. Then, the numerical

115   implementation in CORE[2D]V5 is described. Several verification and benchmarking cases are

116   presented later. Afterwards, the reactive transport model of the long-term geochemical evolution

117   of a radioactive waste repository in clay is presented.

118   **2.   Mathematical formulation**

119   CORE[2D]V5 is a numerical code that solves simultaneously the equations governing groundwater

120   flow, heat transport and geochemically-reactive solute transport. The water flow in variably

121   saturated porous media is given by (Xu et al., 1999):

122   $$\nabla \cdot [K_r \boldsymbol{K} \nabla (\Psi + z)] + w = \left(\phi \frac{\partial S_w}{\partial \Psi} + S_w S_s \right) \frac{\partial \Psi}{\partial t} \tag{1}$$

123 The definition of all the symbols used can be found in the Nomenclature. When the diffusion and

124 dispersion coefficients are similar for all the aqueous species, the reactive transport equations can

125 be expressed in terms of total dissolved component concentrations, C_k, (Xu et al., 1999):

126 $$\nabla \cdot (\theta \boldsymbol{D} \nabla C_k) - \boldsymbol{q} \nabla (C_k) + w(C_k^* - C_k) + \theta R_k = \frac{\partial (\theta C_k)}{\partial t} \qquad k = 1, 2, \dots, N_c \qquad (2)$$

127 The set of geochemical reactions consists of: homogeneous reactions such as aqueous

128 complexation, acid-base and redox reactions and heterogeneous reactions such as mineral

129 precipitation/dissolution, cation exchange, surface complexation and gas dissolution/exsolution

130 reactions. The aqueous chemical system is described in terms of N_c primary species. The rest of

131 the species, known as secondary species, can be represented as linear combinations of the primary

132 species. The total dissolved concentration of a primary species is given by (Xu et al., 1999):

133 $$C_k = c_k + \sum_{j=1}^{Nx} v_{jk} x_j = c_k + \sum_{j=1}^{Nx} v_{jk} \left(K_j^{-1} \gamma_j^{-1} \prod_{i=1}^{Nc} c_i^{v_{ji}} \gamma_i^{v_{ji}} \right) \qquad (3)$$

134 Heat is transported in the water-solid matrix system by groundwater flow and thermal conduction

135 through the fluid and the solid. The heat transport equation is given by (Samper et al., 2011):

136 $$\nabla(\lambda \nabla T - \rho c_w \boldsymbol{q} T) = \theta \rho c_w \frac{\partial T}{\partial t} + (1 - \theta) \rho_s c_s \frac{\partial T_s}{\partial t} = \rho_m c_m \frac{\partial T}{\partial t} \qquad (4)$$

137 CORE^{2D}V5 considers the changes in porosity and updates flow, transport and chemical

138 parameters. The porosity, ϕ, is updated each time step from the computed values of the mineral

139 volume fractions, f_m, according to:

140 $$\phi = 1 - \sum_{m=1}^{N_p} f_m \qquad (5)$$

141 The changes in the permeability are calculated from the Kozeny-Carman equation (Carman,

142 1937). This is one of the most widely accepted permeability-porosity relationships which relates

143 the properties of the porous medium to the flow resistance in pore channels. The Kozeny-Carman

144 equation provides an expression to relate the permeability, k, to the porosity through:

145 $\quad k = k_0 \frac{(1-\phi_0)^2}{(1-\phi)^2}\left(\frac{\phi}{\phi_0}\right)^3$ (6)

146 The pore diffusion coefficients are updated by using the Archie's law (Archie, 1942) which

147 describes the ratio between the effective diffusion of a solute in a porous medium and its diffusion

148 coefficient in pure water which depends on the tortuosity of the medium and the constrictivity.

149 This ratio is often described in terms of the geometrical factor:

150 $\quad \frac{D_e}{D_0} = \frac{\delta}{\tau} = \phi^m$ (7)

151 CORE^{2D}V5 uses the following kinetic rate law for mineral dissolution/precipitation reactions:

152 $\quad r_m = s_m k_m e^{\frac{-Ea}{RT}}\left(\prod_{i=1}^{N_C+N_X} a_i^{p_{mi}}\right)\left(\Omega_m^{\Theta_m}-1\right)^{\eta_m}$ (8)

153 The specific surface of the minerals in saturated porous media (expressed as the surface of mineral

154 per unit volume of water) is updated each time step according to:

155 $\quad A_m^{t+1} = A_m^t \frac{\phi^t}{\phi^{t+1}}$ (9)

156 Eqs (6), (7), (9) are commonly used in reactive transport models based on the continuum

157 approach to update flow and transport parameters from the changes in porosity provoked by

158 mineral dissolution/precipitation (Steefel et al., 2015; Hommel et al. 2018; Poonoosamy et al.,

159 2018). Although these empirical relationships may not be physically representative of the pore-

160 scale processes (Seigneur et al., 2019), they have proven useful to provide a quantitative

161 interpretation of observational data under dynamic conditions.

162 **3. Numerical implementation in CORE^{2D}V5**

163 CORE^{2D}V5 uses a Sequential Iteration Approach (SIA) to solve the coupled solute transport

164 equations and hydrogeochemical reactions. In this approach, transport and chemical equations are

165 treated as two different systems which are solved separately in a sequential iterative process (Xu

166 et al., 1999; Samper et al., 2011). The set of chemical equations is solved on a node basis after

167 solving the transport equations. The resulting non-linear equations are solved with an iterative

168 Newton-Raphson method.

169 CORE^{2D}V5 has been extended to consider the PFE. It should be noticed that the computational

170 work increases when the PFE is considered. Alternatively, CORE^{2D}V5 can also compute the

171 changes in porosity from changes in mineral volume fractions without considering the PFE. If the

172 porosity feedback is modeled, the code checks that the sum of the porosity and the mineral volume

173 fractions is equal to 1 in all the nodes of the grid. In addition, a minimum threshold porosity for

174 clogging is defined by the user.

175 The porosity is updated each time step according to Eq. (5). Minerals are not allowed to precipitate

176 anymore when the porosity is smaller than the threshold porosity. However, mineral dissolution

177 is still allowed although porosity reaches the threshold value. Permeability is updated in the flow

178 equation each time step based on the Kozeny-Carman equation (see Eq. (6)). Nodal water volumes

179 are updated with the most recent values of the porosities after solving the flow equations.

180 Groundwater velocities which are required to evaluate advective and dispersive solute and heat

181 fluxes are calculated from nodal heads by direct application of Darcy's Law to the finite element

182 solution. Diffusion coefficients are updated according to Archie's law (see Eq. (7)). The

183 concentrations of dissolved species are calculated in mol per unit volume of water. Nodal water

184 volumes and the concentrations of dissolved are updated each time step to account for the changes

185 in the porosity. Mineral specific surfaces in saturated porous media are updated each time step

186 according to Eq. (9). Model results related to the changes in porosity are printed out over time in

187 selected output files created by CORE^{2D}V5.

188 Fig. 1 shows the main flowchart of CORE^{2D}V5 with an indication of the main modifications

189 performed in the code to consider the PFE.

190 **4. Verification**

191 **4.1. Verification with analytical solutions**

192 The improvements implemented in CORE[2D]V5 have been verified with the analytical solutions

193 presented by Hayek et al. (2011, 2012). They provided a general methodology to derive analytical

194 solutions for diffusive transport of aqueous species coupled to dissolution/precipitation of a single

195 mineral with a strong PFE. They also reported several examples for 1-D and 2-D systems to use

196 analytical solutions for code benchmarking. CORE[2D]V5 was verified with the analytical solutions

197 for a mineral $M_{(s)}$ initially at chemical equilibrium with two aqueous species $A_{(aq)}$ and $B_{(aq)}$. Then,

198 $M_{(s)}$) dissolves with a kinetic control according to the following chemical reaction:

199 $$A_{(aq)} + B_{(aq)} \leftrightarrow M_{(s)} \qquad (10)$$

200 The analytical solutions assume that solute diffusion is the only transport mechanism. The

201 effective diffusion coefficient is assumed to be proportional to porosity ($D_e = D_0\,\phi$). The

202 following kinetic mineral dissolution/precipitation rate law is used:

203 $$R_m = r_m A_m \left[1 - \frac{c_1 c_2}{K}\right] \qquad (11)$$

204 where c_1 and c_2 are the concentrations of species A and B, respectively, and A_m is the solid reactive

205 surface area which is equal to $A_0\,\phi$, where A_0 is a constant.

206 **4.1.1. 1-D verification test case**

207 The results computed with the 1-D numerical model performed with CORE[2D]V5 were compared

208 with the analytical solutions of Hayek et al. (2011) (see Eq. (A.1), Eq. (A.2) and Eq. (A.3) in the

209 Supplementary Material). The model domain has a length equal to 0.05 m and it was discretized

210 with a regular 1-D finite element grid with 50 elements and 51 nodes. The concentration of the

211 species B is uniform in space and constant in time ($c_2 = 1$ mol/ kg H_2O). Initially, each node of

212 the grid has a different value of c_1 and ϕ. In addition, c_1 is fixed at the boundaries of the model (x

213    $= 0$ and $x = 0.05$ m) with time functions obtained from Eq. (A.1). The simulation was run for 10^5

214   s with time increments of 1 s. 1-D model parameters are listed in Table 1.

215   The computed concentration profiles of species A at several times agree with those calculated

216   with the analytical solutions (see Fig. 1S in the Supplementary Material). c_1 at the left boundary

217   increases with time while it remains unchanged at the right boundary. Fig. 2 shows the comparison

218   of the computed and analytical porosity profiles. Numerical and analytical solutions agree very

219   well. The porosity at the left boundary of the model decreases considerably with time, reaching

220   very small values (clogging).

221   The computed mineral concentration (in mol/m^3 of fluid and in mol/m^3 of rock) were also

222   compared with analytical solutions (see Fig. 3 and Fig. 2S). The results computed with

223   CORE^{2D}V5 agree with the analytical solutions. The mineral concentration in mol per m^3 of fluid

224   volume near the left boundary reaches very high values while the mineral concentration in mol

225   per m^3 of rock volume reaches a constant value when the porosity tends to zero.

226   The significance of the PFE is illustrated by comparing the porosity and the mineral concentration

227   profiles computed with and without the PFE (Fig. 2 and 3). The porosity decreases more quickly

228   in the run without the PFE. The extent of the model in which the clogging occurs in the run

229   without the PFE is larger than in the run with the PEF. The PFE is particularly relevant in models

230   with mineral dissolution/precipitation reactions leading to strong changes in porosity.

231   **4.1.2. 2-D verification test case**

232   The improvements implemented in CORE^{2D}V5 for two-dimensional problems have been verified

233   with an exact analytical solution proposed by Hayek et al. (2012). The 1 m x 1 m model domain

234   was discretized with a triangular mesh with 736 elements and 406 nodes (Fig. 3S). The simulation

235   was performed for $1.5 \cdot 10^7$ s. The time domain was divided into 1500 time periods which in turn

236   were subdivided into 100 time increments.

237   406 different mineral zones and initial waters were defined in the numerical model (one per node)

238   to define the initial porosities and the nodal concentrations of species A and B obtained from Eq.

239   (A.4), Eq. (A.5) and Eq. (A.6) (see Appendix A in the Supplementary Material). The time

240   functions calculated with Eq. (A.4) and Eq. (A.5) were used to prescribe the concentrations c_1 and

241   c_2 at the nodes located along the boundaries of the model, respectively. 2-D model parameters are

242   listed in Table 1.

243   Fig. 4S and Fig. 5S show the comparison of the analytical and numerical concentration profiles

244   of species A and B along the first 40 cm of the diagonal of the model domain for selected times.

245   c_1 and c_2 at the lower left corner increase with time while they remain constant in the middle of

246   the domain ($c_2 \approx 2c_1$). The numerical solutions coincide with the analytical solutions. The product

247   of c_1c_2 increases exponentially at the lower left corner of the model domain. Consequently, the

248   mineral $M_{(s)}$ precipitates strongly at the lower left corner because $c_1c_2 > K$ (see Eq. 11). Fig. 4

249   shows 3-D plots of the spatial distribution of the porosity computed with the analytical and

250   numerical solutions at $5 \cdot 10^6$ s and $1.5 \cdot 10^7$ s. The porosity at the lower left corner of the model

251   domain at the end of the simulation is very small (pore clogging).

252   A simulation run was performed with CORE^{2D}V5 without the PFE. The model results computed

253   with and without the PFE at early times ($t = 5 \cdot 10^6$ s) are similar. Later, the differences in model

254   results increase. The porosity decreases more quickly in the run without the PFE (Fig. 4). Fig. 5

255   shows the comparison of the porosity profiles computed with and without the PFE and the

256   analytical solutions along the first 40 cm of the main diagonal of the model. Porosities computed

257   with the PFE fully agree with those of the analytical solutions. However, the analytical and

258   numerical solutions show significant differences when the PFE is not considered. The clogging

259   effect is more important in the run without the PFE because the mineral precipitation is not

260   restricted in this run.

261   **4.2. Benchmarking**

262   The previous analytical solutions correspond to initial and boundary conditions which are not

263   typical of natural systems. CORE^{2D}V5 was verified also with a more realistic benchmark test case

264   proposed by Xie et al. (2015). This benchmark considers 1D advective-dispersive transport,

265   aqueous complexation and calcite and gypsum dissolution/precipitation. The Kozeny-Carman

266   relationship and the Archie's law are used to relate the permeability, the tortuosity and the pore

267   diffusion coefficient to the porosity, respectively. The simulation was performed at standard

268   pressure (atmospheric pressure) and temperature (25º C) and water saturated conditions. The

269   model domain is 2 m long. It was discretized with a uniform grid size of 0.125 m. The initial

270   porosity and hydraulic conductivity are uniform and equal to 0.35 and 1.16·10^{-4} m/s, respectively.

271   The initial hydraulic head is equal to 0 in all the nodes of the grid. The hydraulic head is prescribed

272   at the inflow (0.007 m) and outflow (0 m). The following kinetic rate law was used for mineral

273   dissolution/precipitation reactions (Xie et al., 2015):

274     $R_m = -r_m[1 - \Omega_m]$ (12)

275   where r_m is rate constant for gypsum (a newly-formed mineral) which is updated as a function of

276   the mineral volume fraction of calcite according to (Lichtner, 1996):

277     $r_m^t = -r_m^0 \left(\frac{f_m^t}{f_m^0}\right)^{\frac{2}{3}}$ (13)

278   Mineral parameters are listed in Table 2.

279   The simulation was performed for a time period of 1000 years. A sulfuric acid solution flows into

280   the porous column containing initially calcite ($f_m^0 = 0.30$ m^3/m^3). The initial pore water is at

281   chemical equilibrium with respect to calcite and undersaturated with respect to gypsum. The

282   model accounts for five primary species and 13 aqueous complexes. The chemical composition

283   of the initial and boundary waters are listed in Table 3. Table 4 lists the equilibrium constants and

284   the aqueous complexation and mineral dissolution/precipitation reactions at 25 ºC.

285   CORE^{2D}V5 was verified with the model results computed with the code MIN3P (Xie et al., 2015).

286   Fig. 6 shows the comparison of the porosity profiles computed with MIN3P and CORE^{2D}V5 at

287   10, 100 and 1000 years. Initially, the porosity is uniform and equal to 0.35. Later, the porosity

288   changes due to the inflow of the acidic solution which leads to calcite dissolution and gypsum

289   precipitation (see Fig. 7 and Fig. 8). Model results show a calcite dissolution front near the inflow

290   boundary. Therefore, the porosity increases in the first 0.2 m of the model domain and reaches a

291   value equal to 0.65 after 10 years. The porosity at $x = 0.2$ m, however, declines due to gypsum

292   precipitation. The volume fraction of gypsum computed with CORE^{2D}V5 at $x = 0.2$ m is slightly

293   larger than that computed with MIN3P. Xie et al. (2015) reported some differences among codes

294   in this point. After 100 years, the length of the model where the porosity is equal to 0.65 increases

295   due to the advance of the calcite dissolution front. The precipitation of gypsum causes the

296   reduction of porosity and clogging occurs at $x = 0.425$ m. After 1000 years, the dissolution front

297   of calcite does not advance due to the clogging. The porosities and the volume fractions of calcite

298   and gypsum computed with CORE^{2D}V5 generally coincide with those calculated with MIN3P.

299   The hydraulic conductivities and the hydraulic heads computed with CORE^{2D}V5 are similar to

300   those computed with MIN3P (see Fig. 9 and Fig. 6S). Clogging occurs at $t = 100$ years and causes

301   a sharp decline of hydraulic heads and a drastic reduction in hydraulic conductivity at $x = 0.425$

302   m. The water outflow through the right boundary of the model is also affected by clogging (Fig.

303   7S). The calculated outflow decreases rapidly after 50 years of simulation. The time evolution of

304   the water outflow computed with CORE^{2D}V5 coincides with that of MIN3P.

305

306

5.   Reactive transport modeling of a radioactive waste repository in clay

307

308   The model of Mon et al. (2017) has been extended by considering the PFE with $CORE^{2D}V5$. The

309   results calculated with and without the PFE have been compared up to $t = 4 \cdot 10^4$ years. This time

310   was selected because the thermal gradients dissipate fully after $2 \cdot 10^4$ years and the changes in

311   porosity become especially relevant also after such period of time. The same spatial discretization

312   has been used in both models to make more reliable the model intercomparison in the clogging

313   zones (Marty et al., 2009). The model reported by Mon et al. (2017) corresponds to a radioactive

314   waste repository in clay according to the Spanish Reference Concept. The waste is confined in

315   cylindrical carbon steel canisters (0.9 m diameter) emplaced in horizontal galleries excavated in

316   the clay formation. The galleries are protected with a 0.3 m thick concrete support. The canisters

317   are surrounded by a 0.75 m thick bentonite barrier. The model assumes axial symmetry with

318   respect to the gallery axis (Fig. 10). The numerical model takes into account the time evolution

319   of the temperature in the repository (see Fig. 8S).

320   The reactive transport model considers the following chemical reactions: 1) Canister corrosion,

321   2) Aqueous reactions such as acid/base, redox and aqueous complexation reactions, 3) Surface

322   complexation of Fe^{2+} and H^+ on three types of sorption sites; 4) Cation exchange of Ca^{2+}, Mg^{2+},

323   Na^+, K^+ and Fe^{2+} and 5) Dissolution/precipitation of 16 minerals. The aqueous chemical system

324   includes 58 aqueous complexes and the following primary species: H_2O, Cl^-, SO_4^{2-}, HCO_3^-,

325    $AlOH_4^-$, H^+, Ca^{2+}, Mg^{2+}, Na^+, K^+, Fe^{2+}, $SiO_2(aq)$ and $O_2(aq)$. All the reactions are assumed at local

326   chemical equilibrium, except for smectite dissolution and canister corrosion. The corrosion rate

327   is 2 μm/year. The thermal and hydrodynamic model parameters are listed in Table 5. More details

328   about the model can be found in Mon et al. (2017).

329   The porosity in the model calculated with $CORE^{2D}V5$ is updated according to Eq. (5). The

330   porosity is not allowed to be less than a threshold value. As an educated guess, this threshold is

331   taken equal to 10^{-4}. The pore diffusion coefficients and the solute tortuosities are updated based

332   on Archie's law with a cementation exponent equal to 4/3 (Millington and Quirk, 1961; see Eq.

333   (7)). Other flow, transport and chemical parameters such as nodal volumes, water velocities,

334   mineral surface areas and nodal dissolved concentrations are also updated every time step to

335   account for the changes in porosity. The dynamic update of the flow and transport parameters

336   from changes in porosity is carried out in the bentonite, concrete and clay. The PFE is not taken

337   into account in the nodes of the grid that simulate the canister.

338   Fig. 11 illustrates the radial distribution of the porosity at $t = 4 \cdot 10^4$ years computed with and

339   without the PFE. Pore clogging in the concrete at $t = 4 \cdot 10^4$ years is predicted from $r = 1.33$ m to

340     $r = 1.34$ m with the PFE and from $r = 1.24$ m to $r = 1.28$ m without the PFE. The pore clogging

341   computed in the concrete near the clay interface is 2.5 cm without the PFE and clogging does not

342   occur in the model with the PFE. The clogging thickness in the clay near the concrete interface is

343   0.8 cm and 1.7 cm with and without the PFE , respectively. Magnetite precipitation at the canister-

344   bentonite interface ($r = 0.45$ m) causes pore clogging at $t = 4 \cdot 10^4$ years in the model without the

345   PFE. However, porosity clogging does not occur in this area in the model with the PFE. The

346   changes in porosity computed with the PFE greatly influence the radial distribution of the

347   effective diffusion after $4 \cdot 10^4$ years (Fig. 9S).

348   The diffusion coefficient of the bentonite near the canister interface is reduced in the model with

349   the PFE, causing that the precipitation of magnetite in the nodes of the canister near the canister-

350   bentonite interface computed in the model with PFE is larger than in the model without PFE. For

351   the same reason, model results with PFE show less magnetite precipitation in the bentonite near

352   the canister interface than those without the PFE (see Fig. 13).

353   Fig. 12, Fig. 10S and Fig. 11S show the time evolution of the concentration of the cumulative

354   mineral precipitation/dissolution in the bentonite (near the concrete interface at $r = 1.125$ m), the

355   concrete (midpoint at $r = 1.35$ m) and the clay (near the interface at $r = 1.525$ m) computed with

356   and without the PFE. Negative (positive) values correspond to mineral dissolution (precipitation).

357   Model results with the PFE show less brucite precipitation in the bentonite near the concrete

358   interface ($r = 1.125$ m). Portlandite dissolution in the concrete midpoint computed with the model

359   without the PFE is slightly faster than that computed with the PFE. All the portlandite is dissolved

360   after $2 \cdot 10^4$ years in the model without the PFE and after $2.5 \cdot 10^4$ years in the model with the PFE.

361   There are significant differences between the time evolution of the cumulative gypsum, brucite,

362   sepiolite and calcite precipitation computed with and without PFE in the clay near the concrete

363   interface ($r = 1.525$ m). Brucite starts precipitating during the first 10^4 years and later dissolves

364   until $t = 3.5 \cdot 10^4$ years in the model with the PFE. Brucite precipitates slightly in the model with

365   the PFE. Sepiolite precipitates in both simulations. However, the precipitation of sepiolite

366   computed without the PFE is slightly larger than that of the model with the PFE. Gypsum

367   precipitates at $t = 10^3$ years and dissolves later at $t = 10^4$ years in the simulation with the PFE.

368   Calcite precipitates in both simulations. The precipitation of calcite in the model without the PFE

369   is larger than in the model with the PFE during the first $2.4 \cdot 10^4$ years. Then, the precipitation of

370   calcite in the model with the PFE is larger than in the model without the PFE.

371   Fig. 13 shows the mineral volume fractions at $t = 4 \cdot 10^4$ years computed with and without the PFE.

372   The model with the PFE calculates less magnetite precipitation than the model without the PFE

373   at the bentonite-canister interface. After $4 \cdot 10^4$ years, there is still portlandite in the concrete, from

374     $r = 1.23$ m to $r = 1.3$ m, in the model without the PFE whereas portlandite remains from $r = 1.24$

375   m to $r = 1.35$ m in the model with the PFE. The results with the PFE show less precipitation of

376   gypsum, brucite, sepiolite and analcime and more precipitation of calcite than those calculated

377   without the PFE near the concrete-clay interface. The differences in the precipitation of brucite

378   and sepiolite affect the pH after $4 \cdot 10^4$ years at both sides of the concrete-clay interface (see Fig.

379   14). Most of the published papers have addressed the PFE under isothermal conditions. The

380   evaluation of the performance of geological radioactive waste disposal facilities requires the use

381   of non-isothermal geochemically-reactive transport models because the radioactive waste

382   generates heat and the thermal field and the temperature gradients may prevail for several

383   thousands of years. Fig. 14 illustrates clearly that the long-term evolution of the pH is clearly

384   affected by the temperature field for both constant and variable porosity models. These

385   predictions are consistent with the numerical findings of Samper et al. (2018) and experimental

386   observations of Lalan et al. (2016) which show that the temperature plays an important role in the

387   degradation of calcium silicate hydrate phases and the precipitation of mineral phases. The

388   changes in porosity for constant temperature are smaller than those computed under

389   nonisothermal conditions. Therefore, it can be concluded that there is a synergetic effect of

390   temperature and clogging.

391   The volume of the precipitated minerals may exceed the porosity of the medium in the most

392   reactive areas of the model domain. The model accounting for the PFE updates dynamically the

393   porosity and ensures that the total mineral volume fraction of the precipitated minerals does not

394   exceed the porosity. The model without the PFE, on the other hand, does not check whether the

395   total mineral volume fractions of the precipitated minerals exceed the porosity. The model results

396   computed with the model with the PFE are more realistic. A significant part of the differences

397   between the results computed with and without the PFE are related to the restriction in the porosity

398   imposed in the model which accounts for the PFE. The changes in the diffusion coefficient due

399   to changes in the porosity is another cause of the differences.

400   Although the mineral evolution computed with the model of the PFE show trends similar to those

401   of the model without the PFE, the results of both models show significant differences. Magnetite

402   precipitation in the model with the PFE is smaller than that computed with the model without the

403   PFE near the bentonite-canister interface due to the decrease of the diffusion coefficient in this

404   interface which favors more magnetite precipitation in the canister and no clogging at the

405   bentonite-canister interface. The pH in the concrete front computed with the model with the PFE

406   is sharper than that computed with the model without the PFE due to the drastic reduction in the

407   diffusion coefficient caused by the decrease in porosity. The total amounts of brucite, sepiolite

408 and gypsum precipitation at the concrete-clay interface computed with the model with the PFE is

409 smaller than those computed with the model without the PFE due to the restriction on the porosity.

410 For the most part, the concentrations of dissolved components computed with and without the

411 PFE at t = $4\cdot10^4$ years are similar. The radial distribution of solute concentrations show jumps at

412 the location of pore clogging in the concrete (r = 1.35 m). These jumps are generally small except

413 for dissolved SO_4^{2-} y $Al(OH)_4^-$ which show large jumps due to solute accumulation in the

414 bentonite.

6. Conclusions

416 Most reactive transport models assume transport and chemical parameters such as porosity,

417 permeability, pore diffusion coefficient and reactive surface areas of minerals remain constant in

418 time. The significance of the dynamic upgrade of the flow, transport and chemical parameters in

419 reactive transport models with mineral dissolution/precipitation has been investigated. The water

420 flow, heat transport and geochemically-reactive solute transport code, CORE[2D]V5, has been

421 extended to take into account the PFE caused by mineral dissolution/precipitation reactions and

422 update the flow, transport and chemical parameters. The porosity is updated each time step based

423 on the changes in the volume fractions of the minerals computed in the previous time step. The

424 permeability is updated by using a Kozeny-Carman equation while diffusion coefficients and

425 tortuosities are updated according to Archie's law.

426 The improvements implemented in CORE[2D]V5 have been verified with analytical solutions for

427 diffusion problems coupled with dissolution/precipitation reactions and feedback of the changes

428 in porosity in 1D and 2D. In addition, CORE[2D]V5 has been verified against the numerical

429 solutions of other reactive transport codes for a benchmark test case involving advective transport

430 in a saturated medium with aqueous complexation and kinetic mineral dissolution/precipitation.

431 The model results computed with CORE[2D]V5 reproduce the analytical solutions and the

432 numerical solutions computed with other reactive transport codes.

433 The numerical solutions computed with the updated version of CORE^{2D}V5 have been used to

434 illustrate the significance of the PFE for several tests cases. Although model results computed

435 with and without the PFE are similar at early times, they show large differences at late times. The

436 PFE is particularly relevant in problems with mineral dissolution/precipitation leading to strong

437 changes in porosity. The porosity decreases more quickly when the PFE is not taken into account.

438 The thickness of the clogging zones computed without the PFE is larger than that computed with

439 the PFE.

440 The updated version of CORE^{2D}V5 has been used to model the non-isothermal chemical

441 interactions of compacted bentonite, corrosion products and concrete in a radioactive waste

442 repository in clay by taking into account the PFE. The major differences of the porosity computed

443 with and without the PFE occur in the concrete and at the concrete-clay and canister-bentonite

444 interfaces. The thickness of pore clogging in the concrete and in the concrete-clay interface

445 computed with the PFE is smaller than that computed without the PFE. The zones affected by

446 clogging in the concrete at $t = 4 \cdot 10^4$ years computed with and without the PFE are 1 and 4 cm

447 thick, respectively. The thickness of clay affected by clogging near the concrete interface is 0.8

448 cm with the PFE while it is 1.7 cm without the PFE. In addition, there are zones affected by pore

449 clogging in the concrete near the clay interface and at the canister-bentonite interface in the model

450 without the PFE. However, porosity clogging does not occur in these areas in the model with the

451 PFE. On the other hand, there are significant differences in the mineral volume fractions

452 computed with and without the PFE after $4 \cdot 10^4$ years. The model with porosity the PFE calculates

453 less magnetite precipitation than the model without the PFE at the bentonite-canister interface.

454 The patterns of portlandite dissolution in the concrete computed with and without porosity the

455 PFE show differences. The model results computed with the PFE show less precipitation of

456 gypsum, brucite, sepiolite and analcime and more precipitation of calcite at the concrete-clay

457 interface than those calculated without the PFE. The largest differences in the computed pH after

458 $4 \cdot 10^4$ years occur at both sides of the concrete-clay interface.

459 The reactive transport models presented here demonstrated that the dynamic update of flow and

460 transport parameters is especially relevant in long-term problems with mineral

461 dissolution/precipitation reactions leading to strong changes in porosity. Modeling tools should

462 take into account the PFE when modeling both engineered systems and natural environments

463 where transport and chemical properties can vary significantly in space and time such as

464 radioactive waste disposal facilities, mine waste deposits and karst systems. However, numerical

465 simulations with the PFE have significant uncertainty. Realistic simulations of the changes in

466 porosity and clogging processes will require long-term experimental data to support model

467 results. Unfortunately, such experimental data are not widely available despite the significant

468 advances made recently in pore scale investigations. The conclusions of our numerical

469 simulations are relevant for the performance assessment of the engineered barriers of radioactive

470 waste repositories and will contribute to reduce model uncertainties and support the hypotheses

471 usually made in the evaluation of the long-term safety of the repositories.

472 The long-term geochemical predictions of the radioactive waste repository calculated with the

473 PFE presented here could be improved by: 1) Adopting a dynamic corrosion front to simulate

474 canister corrosion in a more realistic manner; 2) Simulating the dissolution/precipitation of all

475 minerals with kinetic laws and updating the reactive surface areas; and 3) Solving numerical

476 issues and reducing calculation times to take into account the PFE for a longer period of time (1

477 Ma).

478 **Nomenclature**

Latin terms	
A_m	specific surface of the m-th mineral
A_m^t, A_m^{t+1}	specific surface of the m-th mineral at times t and $t+1$
a_i^{pmi}	catalytic effect factor
C_k	total dissolved concentration of the k-th component
C_k^*	dissolved concentration of a fluid source w
c_i	molal concentrations of the i-th primary species
c_w c_s, c_m	specific heat of water, solids and bulk porous medium, respectively
D	dispersion tensor
D_0	pore diffusion coefficient in pure water

D_e	effective diffusion coefficient
Ea	apparent activation energy
f_m	volume fraction of the m-th mineral
f_m^t, f_m^0	volume fractions of the m-th mineral at times t and $t = 0$, respectively
$\boldsymbol{K}$	saturated hydraulic conductivity tensor
K	mineral solubility constant
K_r	relative hydraulic conductivity
k, k_0	permeability and initial permeability, respectively
k_m	kinetic rate constant of the m-th mineral
$\boldsymbol{q}$	Darcy velocity
N_c	number of primary species
N_p	total number of minerals involved in dissolution/precipitation reactions
N_x	number of aqueous secondary species
m	cementation exponent
R	gas constant
R_k	chemical sink/source term of the k-th component
R_m	mineral dissolution/precipitation rate of the m-th mineral
r_m	effective dissolution/precipitation rate
r_m^t, r_m^0	effective dissolution/precipitation rates at times t and $t = 0$, respectively
s_m	factor for dissolution (1) and precipitation (-1) of the m-th mineral
S_w	water saturation degree
S_s	specific storage coefficient
T	temperature
T_s	mean temperature of the solid
t	time
V_m	mineral molar volume
w	fluid sink/source per unit volume of medium
x_j	molal concentration of the j-th secondary species
z	elevation
Greek terms	
γ	activity coefficient
δ	constrictivity
ϕ, ϕ_0	porosity and initial porosity, respectively
ϕ^t, ϕ^{t+1}	porosity at times t and $t+1$, respectively
$\boldsymbol{\lambda}$	thermal conductivity tensor
η_m	empirical parameter of kinetics reactions
ν_{ji}	stoichiometric coefficient of the i-th primary species in the j-th secondary species
θ	volumetric water content
θ_m	empirical parameter of kinetics reactions
ρ, ρ_s, ρ_m	density of water, solids and bulk porous medium, respectively
τ	medium tortuosity
ψ	pressure head
Ω_m	saturation index (= ion activity product divided by the equilibrium constant)
$\nabla \cdot ()$	divergence operator
$\nabla ()$	gradient operator

Fig. 10. Scheme of the multibarrier system of a radioactive waste repository in clay according to the Spanish Reference Concept and 1-D finite element grid which accounts for the canister, the bentonite barrier, the concrete liner and the clay formation (Mon et al., 2017).

Fig. 11. Radial distribution of the porosity at $t = 0$ and $4 \cdot 10^4$ years with and without the without the PFE.
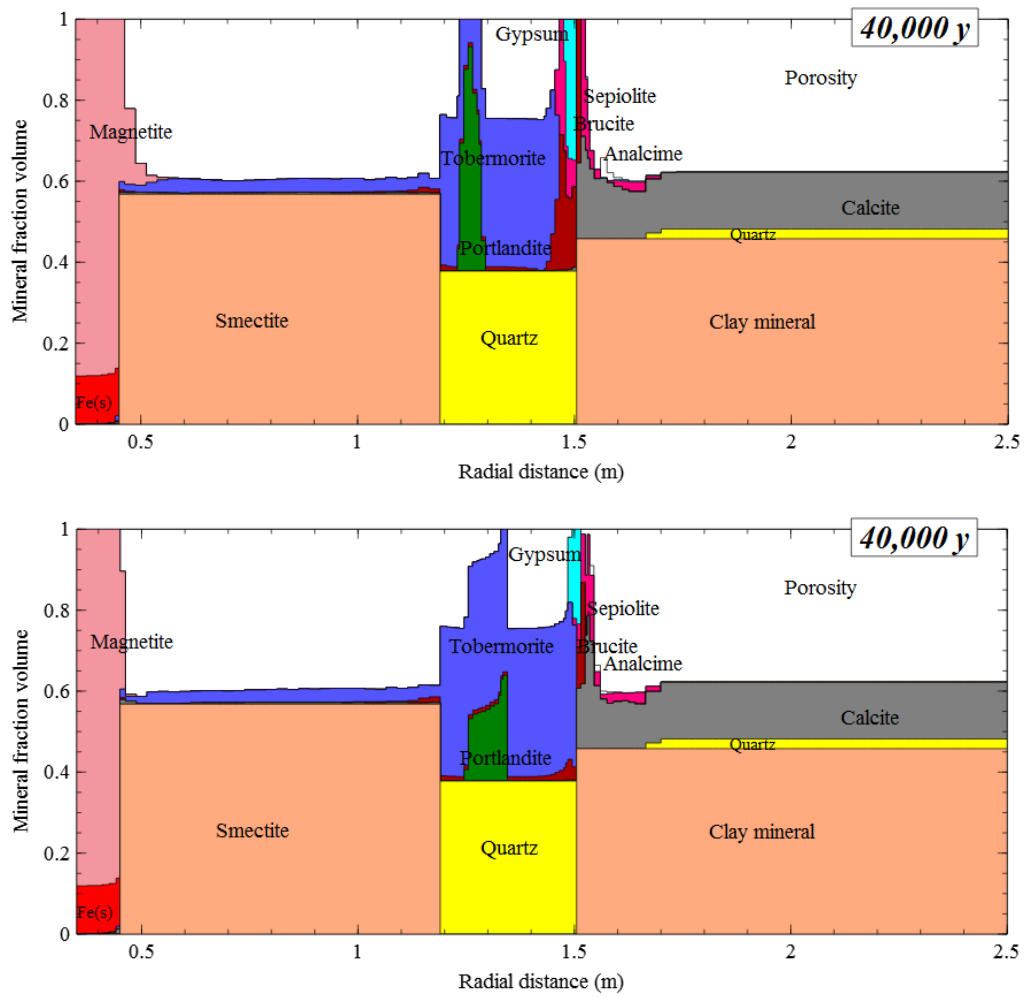

824
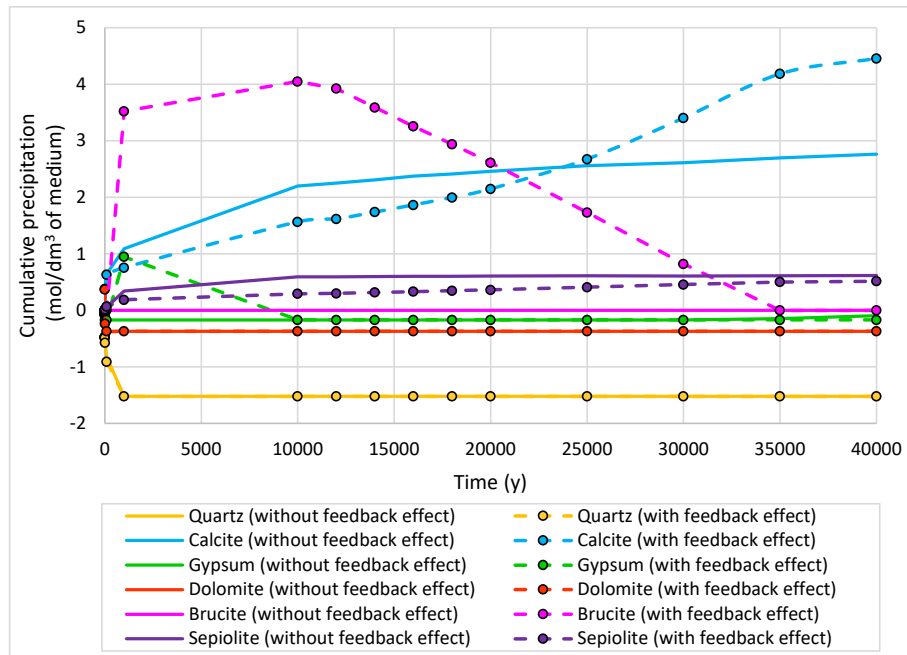

**Fig. 12.** Time evolution of the cumulative mineral dissolution/precipitation in the clay formation near the concrete interface ($r = 1.525$ m) computed with and without the without the PFE (positive for precipitation and negative for dissolution).

829

Fig. 13. Mineral volume fractions at $t = 4 \cdot 10^4$ years computed without (top) and with (bottom) the PFE.

830
831

832

Fig. 14. Radial distribution of the pH computed at $t = 10^4$ years with and without the PFE under non-isothermal conditions and without the PFE under isothermal conditions.

Table 1. Parameters used in 1-D and 2-D numerical models performed to verify the code CORE^{2D}V5 with the analytical solutions (Hayek et al., 2011, 2012).

Parameter	1-D model	2-D model
D_0 (m^2/s)	10^{-9}	10^{-9}
$\log(K)$	-0.16	-0.41
r_m (mol/m^2/s)	10^{-10}	10^{-12}
V_m (m^3/mol)	1	1
A_0 (m^2/m^3)	$5 \cdot 10^3$	10^3

Table 2. Physical and kinetic mineral parameters in the benchmark test case.

Mineral	r_m^0 (m^2 mineral/L bulk)	Density (g/cm^3)	Mol weight (g/mol)	Molar volume (cm^3/mol)	Update type
Calcite	$5 \cdot 10^{-8}$	2.71	100.09	36.93	Two third
Gypsum	$5 \cdot 10^{-8}$	2.32	172.17	74.21	Constant

Table 3. Chemical composition of the initial and boundary waters used in CORE^{2D}V5 in the benchmark test case.

Primary components	Unit	Initial condition	Boundary condition
pH	[-]	9.33	3.0
Ca^{2+}	[mol / L]	$1.70 \cdot 10^{-4}$	$1.00 \cdot 10^{-4}$
CO_3^{2-}	[mol / L]	$2.70 \cdot 10^{-4}$	$1.00 \cdot 10^{-2}$
SO_4^{2-}	[mol / L]	$1.70 \cdot 10^{-4}$	$2.00 \cdot 10^{-1}$
Na^+	[mol / L]	$3.20 \cdot 10^{-4}$	$3.96 \cdot 10^{-1}$

850

851   **Table 4.** Reactions and equilibrium constants for aqueous complexation and mineral
852 dissolution/precipitation reactions at 25ºC used in CORE^{2D}V5 in the benchmark test case
853 (Allison et al., 1991; Xie et al., 2015).

Aqueous complexes	Log K (25ºC)
$CaCO_3(aq) + H^+ \Leftrightarrow Ca^{2+} + HCO_3^-$	7.1100
$CaHCO_3^+ \Leftrightarrow Ca^{2+} + HCO_3^-$	-1.1100
$CaOH^+ + H^+ \Leftrightarrow Ca^{2+} + H_2O$	12.7800
$CaSO_4(aq) \Leftrightarrow Ca^{2+} + SO_4^{2-}$	-2.3090
$CaHSO_4^+ \Leftrightarrow Ca^{2+} + SO_4^{2-} + H^+$	-3.0680
$CO_3^{2-} + H^+ \Leftrightarrow HCO_3^-$	10.3300
$CO_2(aq) + H_2O \Leftrightarrow H^+ + HCO_3^-$	-6.3510
$OH^- + H^+ \Leftrightarrow H_2O$	13.9980
$NaSO_4^- \Leftrightarrow Na^+ + SO_4^{2-}$	-0.7000
$NaCO_3^- \Leftrightarrow Na^+ + CO_3^{2-}$	-1.2680
$NaHCO_3(aq) \Leftrightarrow Na^+ + HCO_3^-$	-0.2500
$H_2SO_4(aq) \Leftrightarrow SO_4^{2-} + 2H^+$	1.0209
$HSO_4^- \Leftrightarrow H^+ + SO_4^{2-}$	-1.9870
Minerals	**Log K (25ºC)**
Calcite $CaCO_3(s) + H^+ \Leftrightarrow Ca^{2+} + HCO_3^-$	1.8550
Gypsum $CaSO_4 \cdot 2H_2O(s) \Leftrightarrow Ca^{2+} + SO_4^{2-} + 2H_2O$	-4.5800

854

855

856

857   **Table 5.** Thermal and hydrodynamic parameters of the canister, the bentonite barrier, the
858 concrete liner and the clay formation.

Parameter	Carbon steel canister	Bentonite barrier	Concrete liner	Clay formation
Hydraulic conductivity (m/s)	$2.75 \cdot 10^{-14}$	$2.75 \cdot 10^{-14}$	$3.39 \cdot 10^{-12}$	$4.19 \cdot 10^{-12}$
Initial porosity	0.407	0.407	0.085	0.37
Effective diffusion (m^2/s)	$4.08 \cdot 10^{-11}$	$4.08 \cdot 10^{-11}$	$8.56 \cdot 10^{-12}$	$5.01 \cdot 10^{-11}$
Density of the solids (kg/m^3)	7860	2700	2513	2778
Specific heat capacity (J/kg^{o}K)	477.66	846.4	1374.32	1118.7
