## S Supporting Information

#### Abstract

Molybdenum disulfide $\left(\mathrm{MoS}_{2}\right)$, a promising two-dimensional transition-metal dichalcogenide, presents a challenge in the tuning of its optoelectronic and chemical properties. Herein, we demonstrate an efficient route to alter the crystalline structure of $\mathrm{MoS}_{2}$ by chemical exfoliation. Using NaK metal alloys, exfoliated and covalently functionalized $\mathrm{MoS}_{2}$ derivatives were obtained with a high metallic (1T) phase ratio, up to $94.5 \%$. Consequently, exfoliated $\mathrm{MoS}_{2}$ showed a significant surface-enhanced Raman scattering activity toward rhodamine 6G (R6G) and crystal violet,  with low detection limits. The versatility of this approach allows the covalent functionalization of $\mathrm{MoS}_{2}$ without relying on edge or basal-plane defects of the structure and preserving the high-ratio 1T phase.

## INTRODUCTION

Since the discovery of graphene, two-dimensional (2D) layered transition-metal dichalcogenides (TMDs) have attracted great attention because of their interesting properties in various application fields, such as electronic and sensor devices, energy-storage, catalysis, and composite materials. ${ }^{1-5}$ Molybdenum disulfide $\left(\mathrm{MoS}_{2}\right)$, one of the most interesting 2D materials, features properties such as a direct band gap (1.9 eV ) and high carrier mobility ( $200-500 \mathrm{~cm}^{2} \mathrm{~V}^{-1} \mathrm{~s}^{-1}$ ), as well as interesting optical properties, such as surface-enhanced Raman scattering (SERS) and high thermal stability. ${ }^{6,7}$
$\mathrm{MoS}_{2}$ is commonly found as a polytype involving the 2 H phase $\left(2 \mathrm{H}-\mathrm{MoS}_{2}\right)$ with semiconducting properties and the 1 T phase ( $1 \mathrm{~T}-\mathrm{MoS}_{2}$ ) with metallic properties. ${ }^{8} 1 \mathrm{~T}-\mathrm{MoS}_{2}$ features conductivity up to $10^{7}$ times higher than $2 \mathrm{H}-\mathrm{MoS}_{2}$, as well as superior charge transfer (CT) ability. Therefore, the metallic phase of $\mathrm{MoS}_{2}$ may find applications including supercapacitors, hydrogen evolution reaction, and SERS. ${ }^{9-12}$

SERS is one of the most selective and ultrasensitive analytical techniques in bioimaging and biosensing ${ }^{13}$ because of the unique vibrational fingerprints of the target molecules and low detection limits. The common SERS phenomenon mainly relies on the so-called electromagnetic (EM) enhancement via localized surface plasmon resonances induced at the surface of metal nanostructures to improve the sensitivity. On the other hand, chemical enhancement (CE) in SERS, which is based on interface dipole-dipole interactions at the substrate as well as CT resonances between the substrate and analyte, is considered as the dominant enhancement mechanism in 2D
materials such as graphene and TMDs. ${ }^{14,15}$ In this context, $\mathrm{MoS}_{2}$ has been shown to display unusually efficient SERSenhancing properties, ${ }^{16}$ with the dominant contribution being supported by CT resonances. The CT mechanism for different dye molecules (copper phthalocyanine, CuPc, rhodamine 6G, R6G, and crystal violet, CV) has been described as a two-step process, where (I) electrons are excited from the highest occupied molecular orbital (HOMO) into the lowest unoccupied molecular orbital of the dye, leaving holes in the HOMO level, and subsequently, (II) electrons migrate from the valence band edge of the $\mathrm{MoS}_{2}$ material into the HOMO, thus recombining with holes. ${ }^{17}$ Thereby, the SERS response significantly depends on the phase state in which the material is presented. Although step (II) in the semiconductor phase requires an extra energy to transfer electrons from the lowlying valence band edge, in the metallic 1 T phase, the higherlying Fermi electrons could migrate without extra energy into the HOMO. The resulting higher electron transition probability leads to a higher SERS enhancement. ${ }^{10,17}$

The preparation of the $\mathrm{MoS}_{2}$ 1T phase with high purity is thus crucial toward improving applications that require high conductivity and effective CT. However, current methods do not allow the production of a pure 1 T phase $\mathrm{MoS}_{2}$ material by any simple approach, because of stability issues and moderately effective processes. ${ }^{8,18,19}$ Ding et al. produced a pure $\mathrm{MoS}_{2} 1 \mathrm{~T}$

[^0]phase by a hydrothermal process in the presence of a magnetic field, using harsh conditions. ${ }^{20}$ In this approach, the considerably high magnetic field (up to 10 T ) and temperature used in the synthesis of $1 \mathrm{~T}-\mathrm{MoS}_{2}$ hinder the applicability of this method and the large-scale production of $1 \mathrm{~T}-\mathrm{MoS}_{2}$. On the other hand, the 1 T phase (octahedral), which is metastable, readily converts into the stable 2 H phase (trigonal prismatic). This limitation has hindered progress regarding the preparation of $1 \mathrm{~T}-\mathrm{MoS}_{2}$. Existing approaches include chemical exfoliation, electron-beam irradiation, electron transfer of plasma hot electrons, mechanical strain, colloidal synthesis, and hydrothermal reaction. ${ }^{8,18}$ Nevertheless, most of the reported methods were shown to produce only mixtures of 1 T and 2 H phase $\mathrm{MoS}_{2}$ nanomaterials.

In general, the most useful and effective methodology to prepare 1T- $\mathrm{MoS}_{2}$ on a large scale is chemical exfoliation. ${ }^{19,21,22}$ In this approach, metal ions ( $\mathrm{M}: \mathrm{Na}, \mathrm{K}$, or Li ) are intercalated between $\mathrm{MoS}_{2}$ layers and then isolated by ultrasound-assisted hydration to achieve the 1 T phase in high yield. The intercalating agents lead to partial conversion of the crystal structure from the 2 H to the 1 T phase, due to electron transfer from the metal ions. ${ }^{23}$ The highest reported 1T phase ratio of $\mathrm{MoS}_{2}$ exfoliated by $n$-butyllithium ( $n$-BuLi), the most common intercalating agent for TMD exfoliation, has been $\sim 60-$ $65 \%{ }^{24,25}$ Recently, the electrochemical exfoliation of $\mathrm{MoS}_{2}$ has also been performed by lithium-ion intercalation under ambient conditions, and the corresponding 1 T phase ratio was only $40 \% .{ }^{26}$ Interestingly, even though metal alloys comprising Na and K are rich electron sources, they remain unexplored in terms of phase engineering for TMDs. ${ }^{27}$

We report herein a highly efficient and simple route to obtain 1T- $\mathrm{MoS}_{2}$ by metal intercalation with NaK alloys, followed by surface functionalization without using structural defects. This reducing agent, which has excessive negative charges, facilitates $\mathrm{MoS}_{2}$ exfoliation, with a significantly higher ratio of 1 T phase compared to previous reports. ${ }^{19,24,25}$ Consequently, the exfoliated $1 \mathrm{~T}-\mathrm{MoS}_{2}$ material was used as a SERS platform for the detection of various probe molecules. Our SERS results demonstrate that $1 \mathrm{~T}-\mathrm{MoS}_{2}$ significantly increases the Raman signal of probe molecules through efficient CT. ${ }^{10}$ Furthermore, the obtained negatively charged $1 \mathrm{~T}-\mathrm{MoS}_{2}$ layers feature the versatility to chemically modify the $\mathrm{MoS}_{2}$ structures for potential sensing applications.

## - EXPERIMENTAL SECTION

General. $\operatorname{MoS}_{2}(\sim 6 \mu \mathrm{~m})$ powder, iodine $\left(\mathrm{I}_{2} ; 99.8 \%\right)$, $n-$ butyllithium ( 2.5 M in hexane), 4-fluoroaniline (99\%), 4-chloroaniline ( $98 \%$ ), 4-bromobenzenediazonium tetrafluoroborate ( $96 \%$ ), and 4-nitrobenzenediazonium tetrafluoroborate (97\%) were purchased from Sigma-Aldrich. All chemicals including organic solvents used in the reaction and purification were purchased from either SigmaAldrich or Alfa-Aesar and used as received. Bulk- $\mathrm{MoS}_{2}$ was prepared from a suspension of $\mathrm{MoS}_{2}$ powder ( 5 mg ) in Milli-Q water ( 5 mL ). The resulting suspension was then sonicated (Ultrasons-H Selecta) for 1 h . Centrifugation was carried out (Heraeus Megafuge 16R) at 500 rpm to precipitate the larger flakes. After centrifugation, the top two-thirds of the dispersion were extracted by a pipet. The obtained suspension was filtered (PTFE Millipore filter, $0.45 \mu \mathrm{~m}$ pore size) and dried under vacuum to obtain bulk- $\mathrm{MoS}_{2}(1 \mathrm{mg})$.

Chemical Exfoliation. $\mathrm{MoS}_{2}$ powder was dried at $150^{\circ} \mathrm{C}$ under vacuum overnight prior to use. Our chemical exfoliating $1 \mathrm{~T}-\mathrm{MoS}_{2}$ preparation was a modification of the method reported by Feng et al. ${ }^{27}$ Briefly, $\mathrm{Na}(35 \mathrm{mg}, 1.5 \mathrm{mmol})$ and $\mathrm{K}(59 \mathrm{mg}, 1.5 \mathrm{mmol})$ metals were mixed with 1,2-dimethoxyethane (DME) solution ( 20 mL ) and vigorously stirred for 2 h at room temperature to obtain a liquid NaK
alloy dispersion with a blue color. Then, $\mathrm{MoS}_{2}$ powder $(160 \mathrm{mg}, 1$ mmol ) is added to this solution, and the mixture is allowed to stir for 24 h . The reaction is then quenched by the addition of $\mathrm{I}_{2}(761 \mathrm{mg} ; 3$ mmol ) to the stirring solution. The mixture is washed three times with cyclohexane/water ( $1: 1, \mathrm{v} / \mathrm{v}$ ) solution and then filtered thoroughly using polytetrafluoroethylene (PTFE; $0.45 \mu \mathrm{~m}$ ) membrane filters with dimethylformamide (DMF; $4 \times 30 \mathrm{~mL}$ ), ethanol ( 2 $\times 20 \mathrm{~mL})$, acetone $(2 \times 20 \mathrm{~mL})$ and water $(2 \times 20 \mathrm{~mL})$.

For comparison, the chemical exfoliation of $\mathrm{MoS}_{2}$ was also performed by $n-\mathrm{BuLi}$, in a similar method as reported by Knirsch et al. ${ }^{24} n$-BuLi solution ( $3 \mathrm{~mL}, 2.5 \mathrm{M}$ in hexane) is added to the 200 mg $\mathrm{MoS}_{2}$ suspension in dry hexane $(10 \mathrm{~mL})$ and allowed to stir under an inert atmosphere for 24 h . The black precipitate was filtered thoroughly with dry hexane to remove the unreacted $n-\mathrm{BuLi}$ and organic impurities and followed by quenching of the reaction with 100 mL of Milli-Q water. The resulting $\mathrm{MoS}_{2}$ suspension was centrifuged at 750 rpm for 1.5 h to remove the nonexfoliated material and then filtered thoroughly using PTFE $(0.45 \mu \mathrm{~m})$ membrane filters with Milli-Q water.

Diazonium Salt Synthesis. 4-Fluorobenzenediazonium tetrafluoroborate and 4-chlorobenzenediazonium tetrafluoroborate were synthesized from precursors such as 4-fluoroaniline and 4-chloroaniline following the published diazotization procedure (Scheme S1). ${ }^{28}$ First, 4-fluoroaniline ( 1 mmol ) was added to into $\mathrm{HBF}_{4}$ aqueous solution ( 0.4 mL ). Then, 40 mL of acetic acid was added and isoamylnitrite $(0.4 \mathrm{~mL} ; 3 \mathrm{mmol})$ solution dissolved in 20 mL acetic acid was slowly added dropwise to the mixture. The reaction was stirred for 15 min at room temperature. The mixture was then quenched by adding of 40 mL of diethyl ether solution and stored at $-22{ }^{\circ} \mathrm{C}$ overnight. The resultant product was filtered via PTFE filter $(0.45 \mu \mathrm{M})$ and then washed several times with diethyl ether. The obtained 4-fluorobenzenediazonium tetrafluoroborate was dried under vacuum at room temperature. The 4-chlorobenzenediazonium tetrafluoroborate was prepared by same diazotization procedure as presented above. The Fourier-transform infrared spectroscopy (FTIR) spectra of 4-fluorobenzenediazonium tetrafluoroborate and 4-chlorobenzenediazonium tetrafluoroborate show the characteristic bands of diazonium salt at around $2270 \mathrm{~cm}^{-1}$ as presented in Figure S1.

Covalent Functionalization. For covalent functionalization of $\mathrm{MoS}_{2}, \mathrm{MoS}_{2}$ intercalated with the NaK alloy as described in the chemical exfoliation paragraph was reacted with 4-fluorobenzenediazonium tetrafluoroborate ( $630 \mathrm{mg} ; 3 \mathrm{mmol}$ ), 4-chlorobenzenediazonium tetrafluoroborate ( $680 \mathrm{mg} ; 3 \mathrm{mmol}$ ), 4-bromobenzenediazonium tetrafluoroborate ( $812 \mathrm{mg} ; 3 \mathrm{mmol}$ ), and 4-nitrobenzenediazonium tetrafluoroborate $(711 \mathrm{mg} ; 3 \mathrm{mmol})$. After the reaction, each of the resulting precipitates were filtered thoroughly using the PTFE $(0.45 \mu \mathrm{~m})$ membrane filters with DMF $(4 \times 30 \mathrm{~mL})$, ethanol $(2 \times 20$ $\mathrm{mL})$, acetone $(2 \times 20 \mathrm{~mL})$, and water $(2 \times 20 \mathrm{~mL})$. The exfoliated and functionalized $\mathrm{MoS}_{2}$ materials were then dried under vacuum for the structural and morphological characterizations.

Characterization of Exfoliated Materials. To evaluate the exfoliation of the bulk crystal of the layered $\mathrm{MoS}_{2}$ precursor (bulk$\mathrm{MoS}_{2}$ ), the exfoliated materials were measured by X-ray diffraction (XRD) and transmission electron microscopy (TEM). XRD analyses were carried out in a Bruker D8 Advance diffractometer with an X-ray source of $\mathrm{Cu} \mathrm{K} \alpha(1600 \mathrm{~W})$. The diffractometer presents BraggBrentano $\theta-\theta$ configuration for powder samples. TEM images were obtained using a JEOL JEM-1400PLUS electron microscope at 120 kV equipped with a GATAN US1000 CCD camera. High-resolution TEM (HRTEM) images and selected area electron diffraction (SAED) patterns were acquired with a JEOL JEM-2100F UHR electron microscope at 200 kV equipped with a TVIPS F-216 CMOS camera. The TEM samples were prepared by drop-casting sample solutions on the ultrathin carbon film-coated Cu-grids (Ted Pella Inc., USA) and desiccated under ambient conditions.

The change of crystallinity was detected by Raman spectroscopy, X-ray photoelectron spectroscopy (XPS) and UV-vis spectroscopy (UV). Raman spectra were recorded with a Renishaw inVia Raman microscope equipped with laser wavelengths $\lambda=532,633$, and 785
nm , a lens-based spectrometer with two gratings ( $1800 \mathrm{gr} / \mathrm{mm}$ for vis and $1200 \mathrm{gr} / \mathrm{mm}$ for near infrared), and a Peltier-cooled frontilluminated CCD (1024 px $\times 532 \mathrm{px}$ ). XPS measurements were performed in a SPECS Sage HR 100 spectrometer with a nonmonochromatic X-ray source of aluminium with a $\mathrm{K} \alpha$ line of 1486.6 eV energy and 300 W . XPS measurements were performed in a SPECS Sage HR 100 spectrometer with a nonmonochromatic X-ray source of aluminium with a $\mathrm{K} \alpha$ line of 1486.6 eV energy and 300 W . The fitting of the XPS data was applied using CasaXPS software. The quantification of the 1 T phase was calculated by the deconvolution of Mo 3s core levels. UV-visible spectra were studied in a Jasco V-630 BIO or Varian Cary 5000 spectrophotometer.

The chemical modification of $\mathrm{MoS}_{2}$ was characterized by Raman spectroscopy, XPS, thermogravimetric analysis (TGA), and FTIR. TGA measurements were performed on a TA Instruments Discovery system under air starting from $100^{\circ} \mathrm{C}$ with ramp of $10^{\circ} \mathrm{C} / \mathrm{min}$ up to $800^{\circ} \mathrm{C}$ after an isotherm at $100^{\circ} \mathrm{C}$ for 20 min . The functionalization degree (FD) for all functionalized samples was calculated by considering the decomposition of $\mathrm{MoS}_{2}$ at $650{ }^{\circ} \mathrm{C}$ in the corresponding TGA profiles (eq 1). FD is expressed in terms of number of $\mathrm{MoS}_{2}$ molecules per introduced functional group. R and L are corresponded to the weight loss (\%) and residue (\%) observed at $650{ }^{\circ} \mathrm{C}$, after having subtracted the analogous loss from the pristine $\mathrm{MoS}_{2}$. The expected moiety on the $\mathrm{MoS}_{2}$ surface is expressed as $\left(M_{\mathrm{w}}\right)$, and the molecular weight of $\mathrm{MoS}_{2}$ determined to be $160.07 \mathrm{~g} /$ mol.

$$
\begin{equation*}
\mathrm{FD}=\frac{R(\%) \cdot M_{\mathrm{w}}(\mathrm{~g} / \mathrm{mol})}{L(\%) \cdot 160.07(\mathrm{~g} / \mathrm{mol})} \tag{1}
\end{equation*}
$$

The FTIR characterization was carried out in transmission mode by means of a Nicolet 6700 spectrometer. For this purpose, solid $\mathrm{MoS}_{2}$ powders $(2 \mathrm{mg})$ were mixed with a 200 mg KBr matrix, stored in the oven at $80^{\circ} \mathrm{C}$, pestle, and pressed to discs (diameter 13 mm ) under 154 MPa using a KBr pellet kit and hydraulic press (Specac).

Elemental analysis was performed using a TRUSPEC CHNS microanalyzer, which is able to determinate the contents of $\mathrm{C}, \mathrm{H}, \mathrm{N}$, and S by combustion of the sample at $1100{ }^{\circ} \mathrm{C}$ under an oxygen atmosphere and with the quantitative detection of the combustion products. Before the sample analysis, the determination of blanks was performed (in absence of samples) to check the detection levels of the device. The maximum values of the verified blanks are the following: $0.06 \%$ for C, $0.16 \%$ of $\mathrm{H}, 0.02 \%$ for N , and $0.35 \%$ for S .

SERS Measurements. The SERS substrates were prepared on $300 \mathrm{~nm} \mathrm{SiO} 2 / \mathrm{Si}$ surfaces after the cleaning procedure with ethanol and Milli-Q water. $\mathrm{NaK}-\mathrm{MoS}_{2}$ and $\mathrm{Li}-\mathrm{MoS}_{2}$ were dispersed in Milli-Q water for 1 h , and then, $\mathrm{MoS}_{2}$ dispersions $\left(1 \mathrm{mg} \mathrm{mL}^{-1}\right)$ were covered by drop casting onto the cleaned $\mathrm{SiO}_{2} / \mathrm{Si}\left(\sim 25 \mathrm{~mm}^{2}\right)$ surfaces. The substrates were dried at room temperature and then incubated in the different concentrations of R6G and CV solutions for 2 h . The R6G and CV-deposited $\mathrm{MoS}_{2}$ substrates were washed with Milli-Q water to remove the free R6G or CV and dried under nitrogen atmosphere. Bulk- $\mathrm{MoS}_{2}$ was also exfoliated by sonication for 1 h to obtain fewlayered material for comparison of the SERS activity with $\mathrm{NaK}-\mathrm{MoS}_{2}$ and $\mathrm{Li}-\mathrm{MoS}_{2}$. Afterward, the bulk $-\mathrm{MoS}_{2}$ substrate was also prepared according to the same preparation procedure mentioned above for SERS measurements. The SERS spectra of so-prepared bulk- $\mathrm{MoS}_{2}$, $\mathrm{NaK}-\mathrm{MoS}_{2}$, and $\mathrm{Li}-\mathrm{MoS}_{2}$ substrates were recorded using a $100 \times$ objective $(N A=0.85)$ at excitation wavelengths of $532 \mathrm{~nm}(0.9 \mathrm{~mW}$ power laser, 30 s of integration time), 633 nm ( 0.9 mW power laser, 30 s of integration time), and $785 \mathrm{~nm}(1.7 \mathrm{~mW}$ power laser, 10 s of integration time in scanning mode). The presented spectra were baseline corrected and normalized to the same laser power and integration time. The enhancement factor (EF) value of the fabricated $\mathrm{MoS}_{2}$ substrates was estimated according to the eq $\mathrm{S} 1 .{ }^{29}$

## - RESULTS AND DISCUSSIONS

Phase Engineering by Chemical Exfoliation. Exfoliated and functionalized $\mathrm{MoS}_{2}$ sheets were synthesized using NaK alloy intercalation (Scheme 1), as detailed in the Experimental

Scheme 1. Schematic Representation of Chemical Exfoliation and Functionalization for $\mathrm{MoS}_{2}$ with High 1T Phase Ratio

section. Briefly, the exfoliation mechanism of bulk- $\mathrm{MoS}_{2}$, which is a 2 H polytype, can be explained by the intercalation of cations between layers of $\mathrm{MoS}_{2} .{ }^{27}$ First, bulk- $\mathrm{MoS}_{2}$ is reduced with solvated electrons, which are generated from the very potent electron source NaK alloy dissolved in DME at room temperature. The initially formed solvated electrons would be consumed by the bulk- $\mathrm{MoS}_{2}$ and further reduction proceeds until the maximum ratio of cations to $\mathrm{MoS}_{2}$ is reached. Thus, the exfoliation process is produced by Coulombic repulsion between layers of reduced $\mathrm{MoS}_{2}$. The negative charges on $\mathrm{MoS}_{2}$ are balanced by solvated and intercalated $\mathrm{Na}^{+}$or/and $\mathrm{K}^{+}$ cations. In addition, the phase of TMDs depends strongly on the d orbital electron density of the transition metal. ${ }^{8}$ As a consequence of the reduction process of bulk- $\mathrm{MoS}_{2}$, the electron density in the d orbital is increased, leading to a strong structural reorientation, from the thermodynamically more stable semiconducting 2 H polytype to the metallic 1 T polytype. Finally, the negatively charged $\mathrm{MoS}_{2}$ is quenched by $\mathrm{I}_{2}$ as electrophile to obtain an exfoliated material $\mathrm{NaK}-\mathrm{MoS}_{2}$ with a high proportion of 1 T phase. For comparison purposes, $\mathrm{MoS}_{2}$ was also exfoliated by $n-\mathrm{BuLi}\left(\mathrm{Li}-\mathrm{MoS}_{2}\right)$ as a conventional intercalating agent for $\mathrm{MoS}_{2}$ exfoliation. ${ }^{21}$

Chemically exfoliated $\mathrm{MoS}_{2}$ was studied by XRD, Raman spectroscopy, XPS, UV, TGA, and TEM. The chemical exfoliation of $\mathrm{MoS}_{2}$ was confirmed by XRD. Figure S2 indicates typical $2 \theta$ values of bulk $\mathrm{MoS}_{2}$ and $\mathrm{NaK}-\mathrm{MoS}_{2}$, with the characteristic sharp (002) diffraction peak of bulk$\mathrm{MoS}_{2}$ at $14.5^{\circ}$, shifted to $14.2^{\circ}$ and broadened (Figure 1A), indicating the expansion of the interlayer distance and successful exfoliation of $\mathrm{MoS}_{2} .{ }^{11,30}$ In addition, TEM images of $\mathrm{NaK}-\mathrm{MoS}_{2}$ demonstrated few layers of $\mathrm{MoS}_{2}$ with relatively small lateral dimensions, in the nanometer size range (Figure S24B). HRTEM images showed well-ordered and welloriented crystalline structuring in the sample, which allows the acquisition of SAED patterns from individual sheets (Figure S25). The crystal structure of $\mathrm{NaK}-\mathrm{MoS}_{2}$ was determined by selected area electron diffraction (Figure S25B), confirming the lattice spacing for our structure to coincide accurately with published reference data for $\mathrm{MoS}_{2} \cdot{ }^{31-33}$

Raman spectroscopy was used to characterize the change in crystallinity. Figure 1B shows the Raman spectra of bulk- $\mathrm{MoS}_{2}$ and $\mathrm{NaK}-\mathrm{MoS}_{2}$ excited at 633 nm . In the spectrum of bulk$\mathrm{MoS}_{2}$, we observed the two main phonon peaks located at $\sim 380$ and $\sim 405 \mathrm{~cm}^{-1}$, arising from the $\mathrm{E}_{2 \mathrm{~g}}$ (in-plane) and $\mathrm{A}_{1 \mathrm{~g}}$ (out-of-plane) vibration modes of $\mathrm{MoS}_{2}$, respectively. In addition, a typical second-order longitudinal acoustic phonon

Figure 1. (A) Magnified XRD patterns of the (002) peaks of bulk- $\mathrm{MoS}_{2}$ and $\mathrm{NaK}-\mathrm{MoS}_{2}$ crystals; (B) Raman spectra of bulk- $\mathrm{MoS}_{2}$ and $\mathrm{NaK}^{2}-\mathrm{MoS}_{2}$ obtained by excitation at 633 nm ; (C,D) XPS core level spectra of Mo 3 d ( $\sim 25 \mathrm{meV}$ shift) and S 2 p ( $\sim 24 \mathrm{meV}$ shift) for bulk-MoS 2 and NaK$\mathrm{MoS}_{2}$.
peak ( $2 \mathrm{LA}(\mathrm{M})$ ) around $\sim 450 \mathrm{~cm}^{-1}$ was also detected. After chemical exfoliation, new peaks were observed at $187,224,289$ $\mathrm{cm}^{-1}$, which correspond to the $\mathrm{J}_{1}-\mathrm{J}_{3}$ phonon modes of NaK$\mathrm{MoS}_{2}$, respectively. These low-frequency phonon modes confirm that $\mathrm{NaK}-\mathrm{MoS}_{2}$ has 1 T phase features, and is in line with the characterization of $\mathrm{Li}-\mathrm{MoS}_{2}$ (Figure S3) and with previously reported values. ${ }^{24,34}$

In the UV spectrum of bulk- $\mathrm{MoS}_{2}$ (Figure S4), the two excitonic $A$ and $B$ bands, which are related to the presence of a highly ordered structure, were observed. ${ }^{35,36}$ These characteristic bands disappeared after exfoliation of $\mathrm{MoS}_{2}$ by NaK alloy, confirming a change in the crystallinity from 2 H to $1 \mathrm{~T} \mathrm{MoS}{ }_{2} .{ }^{17}$

The XPS analysis was employed to obtain the $\mathrm{MoS}_{2} 1 \mathrm{~T} / 2 \mathrm{H}$ ratio, by fitting Mo 3d and S 2p core levels. Sharp Mo 3d signals at 233.05 ( $\mathrm{Mo}_{3} \mathrm{~d}^{3 / 2}$ ) and 229.92 ( $\mathrm{Mo} \mathrm{3d}^{5 / 2}$ ) were observed in bulk- $\mathrm{MoS}_{2}$; however, the corresponding signals after exfoliation were shifted $(\sim 25 \mathrm{meV})$ to lower binding energies, suggesting the existence of both 1 T and 2 H phases after exfoliation (Figure 1C,D). The 1T phase was identified by a shift $(\sim 0.8 \mathrm{eV})$ with respect to that for 2 H phase in the fitting of Mo 3d for $\mathrm{NaK}-\mathrm{MoS}_{2}$. A similar XPS result was obtained for $\mathrm{Li}-\mathrm{MoS}_{2}$ (Figure S5); but deconvolution of the Mo 3d peak shows two new peaks for $\mathrm{MoO}_{3}$ and $\mathrm{MoO}_{2}$ in Li $\mathrm{MoS}_{2}$, whereas $\mathrm{NaK}-\mathrm{MoS}_{2}$ does not display any significant peak from oxidized products of $\mathrm{MoS}_{2}$. We hypothesize that this may be due to the quenching agent $\left(\mathrm{H}_{2} \mathrm{O}\right)$ used in the preparation of $\mathrm{Li}-\mathrm{MoS}_{2} .{ }^{24,34,37}$

Upon deconvolution of the corresponding Mo 3d core level, the 1 T phase ratio was found to be $\sim 94.5 \%$ for $\mathrm{NaK}-\mathrm{MoS}_{2}$ (Table 1). Such a high value indicates that NaK alloy is a suitable intercalating agent, more efficient than Li , and single Na or K. ${ }^{19,22}$ Several factors are crucial for successful exfoliation and phase conversion of TMDs. For instance, Loh et al. reported the high influence of the cation species of

alkali metal naphthalenides in the exfoliation efficiency of TMDs, $\mathrm{Na}^{+}$being more efficient than $\mathrm{Li}^{+}$and $\mathrm{K}^{+} .{ }^{19}$ More recently, Sofer et al. also reported that the cation size of intercalating agents is a dominating factor for phase engineering, with smaller cation species showing a better exfoliation and 1 T phase conversion for electrochemically exfoliated TMDs. ${ }^{22}$ However, other parameters such as dispersibility of intercalating agents must be considered for an efficient chemical exfoliation and phase conversion. Comparing NaK alloy with single Na or K , the alkali alloy (which is a liquid) is more easily dispersed in solution than Na or K solid metals at room temperature under stirring conditions, thus leading to higher intercalation and conversion efficiencies than individual Na or K.

SERS Performance. To show the effect of the phase transition from 2 H to 1 T on the SERS efficiency, a $\mathrm{NaK}-\mathrm{MoS}_{2}$ substrate was prepared on a $300 \mathrm{~nm} \mathrm{SiO}_{2} / \mathrm{Si}^{\text {surface and }}$ compared to $\mathrm{MoS}_{2}$ exfoliated by $n$ - $\mathrm{BuLi}\left(\mathrm{Li}-\mathrm{MoS}_{2}\right)^{21}$ and to bulk- $\mathrm{MoS}_{2}$, in the detection of rhodamine 6G (R6G) and CV

Figure 2. SERS spectra of $10 \mu \mathrm{M}$ R6G (A) and CV (B) on bulk- $\mathrm{MoS}_{2}$ (a), $\mathrm{Li}-\mathrm{MoS}_{2}$ (b), and $\mathrm{NaK}-\mathrm{MoS}_{2}$ (c) substrates, excited by 532 nm laser; SERS spectra of various concentrations of R6G (C) and CV (D), deposited on NaK-MoS ${ }_{2}$.
as target analytes. Figure 2A,B displays the SERS spectra of CV and R6G on three $\mathrm{MoS}_{2}$ modifications excited at 532 nm . The main vibrations of CV were recorded at 1618, 1583, 1378, 1175 (symmetric and asymmetric in-plane CC ring stretch modes), and $914 \mathrm{~cm}^{-1}$ (out-of-plane CC ring bending mode). The most intense R6G vibrations were found at 1647, 1575, 1363 (in-plane CC ring stretch modes), 775 , and $611 \mathrm{~cm}^{-1}$ (out-of-plane CC ring bending modes). The results indicate that exfoliated $\mathrm{MoS}_{2}$ samples provided a significantly higher SERS enhancement than bulk- $\mathrm{MoS}_{2}$ for both probe molecules (Table 2). The EF of the prepared substrates was calculated to

Table 2. Calculated EFs for bulk-MoS ${ }_{2}, \mathrm{Li}_{\mathbf{- M o S}}^{2}$, and NaK$\mathrm{MoS}_{2}$ Substrates on Different Raman Dyes

|  |  | EFs |  |  |
| :---: | :---: | :---: | :---: | :---: |
| dyes | Raman shift $\left(\mathrm{cm}^{-1}\right)$ | bulk-MoS | $\mathrm{Li}_{2}-\mathrm{MoS}_{2}$ | $\mathrm{NaK-MoS}$ |
| R6G | $2.04 \times 10^{3}$ | $1.73 \times 10^{4}$ | $2.92 \times 10^{4}$ |  |
| CV | 611 | 1618 | $2.12 \times 10^{3}$ | $1.39 \times 10^{4}$ |

evaluate their SERS efficiency using $10 \mu \mathrm{M}$ Raman dye solutions, according to the eq S1 (details are given in Supporting Information). $\mathrm{NaK}-\mathrm{MoS}_{2}$ showed an EF 1 order of magnitude higher than bulk- $\mathrm{MoS}_{2}$ and 2 times higher than $\mathrm{Li}-\mathrm{MoS}_{2}$, for both R6G and CV. Interestingly, the difference between the EFs of $\mathrm{NaK}-\mathrm{MoS}_{2}$ and $\mathrm{Li}-\mathrm{MoS}_{2}$ practically coincides with the difference between their 1 T ratios, indicating a higher conductivity which corresponds to a higher-lying Fermi level and provides more efficient CT from the substrate to probe molecules. ${ }^{38,39}$

The SERS performance of the $\mathrm{NaK}-\mathrm{MoS}_{2}$ substrate was also estimated by evaluating the detection limits for R6G and CV. As shown in Figure 2C,D, the SERS intensity is directly correlated to the concentrations of Raman probes. Although Yin et al. and Anbazhangan et al. reported the use of $\mathrm{MoS}_{2}$ with a high 1T phase ratio, as SERS substrates for R6G and CV detection, ${ }^{10,17}$ we demonstrate here superior SERS sensitivities for both R6G and CV, using $\mathrm{NaK}-\mathrm{MoS}_{2}$. The lowest detected
concentrations for R 6 G and CV on $\mathrm{NaK}-\mathrm{MoS}_{2}$ were as low as $10^{-9}$ and $10^{-8} \mathrm{M}$, respectively, which compare favorably with previously reported studies, ${ }^{10,17,40,41}$ and are even comparable to efficient metallic substrates. ${ }^{42,43}$

Trying to understand in more the depth the origin of such an unusually strong SERS effect for $\mathrm{NaK}-\mathrm{MoS}_{2}$, UV, photoluminescence (PL), and Raman scattering were measured. As mentioned above, contributions to SERS may be of both EM nature, due to excitation of localized surface plasmons, and of chemical nature (CE), due to the probesubstrate interactions providing CT and molecular resonances. The EM mechanism can be nearly excluded because of the absence of strong plasmons or excitons in the UV-vis spectrum (Figures 3 and S4). The quenching of the intrinsic absorbance and PL of CV and R6G with increasing $\mathrm{NaK}-\mathrm{MoS}_{2}$ concentration indicates a strong coupling between probe and substrate, leading to effective (nonradiative) CT resonances (Figures S10-S13). Measurements of R6G and CV using 532, 633, and 785 nm excitation wavelengths revealed that only strong SERS signals were recorded when the laser was in resonance with an electronically excited state of the probe, or close to it. In addition, we note that no Raman signals were detected when using other probe molecules such as mercaptobenzoic acid (data not shown), which can be readily measured on metal nanostructures. ${ }^{44-46}$ In conclusion, all these experimental data suggest as the major cause of SERS is the CE mechanism. The molecular resonances were identified by UV-vis spectroscopy to be around 527 nm in R6G (Figure 3A) and around 595 nm , with a prominent shoulder around 545 nm , in CV (Figure 3B). The difference between the UVvis spectra of $\mathrm{NaK}-\mathrm{MoS}_{2}$ in the presence and absence of the dyes did not display new resonances close to the excitation wavelengths, but in the case of CV, the 7 nm (blue) shift of the 545 nm shoulder indicated significant binding of the molecule to the surface, concomitantly pushing the resonance maximum close toward the 532 nm excitation wavelength. This, in turn, could explain the relatively high SERS intensity of CV at 532 nm .

Figure 3. UV-vis absorbance spectra of dye- $\mathrm{NaK}-\mathrm{MoS}_{2}$ (red line) and pure $\mathrm{NaK}-\mathrm{MoS}_{2}$ (black line) suspensions compared to pure dye solutions (green line) containing $1 \mu \mathrm{M}$ R 6 G and $20 \mathrm{mg} \mathrm{mL}^{-1} \mathrm{NaK}-\mathrm{MoS}_{2}$ (A) and $1 \mu \mathrm{MCV}$ and $20 \mathrm{mg} \mathrm{mL}^{-1} \mathrm{NaK}-\mathrm{MoS}_{2}$ (B). Dashed, vertical lines (gray) highlight available laser excitation wavelengths. The difference spectrum between the dye- $\mathrm{NaK}-\mathrm{MoS}_{2}$ and $\mathrm{NaK}-\mathrm{MoS}_{2}$ (purple lines) reveal that the excitation of the molecular resonances of adsorbed dyes is partially quenched by the presence of $\mathrm{NaK}-\mathrm{MoS}_{2}$, indicating effective interaction with the $\mathrm{MoS}_{2}$ substrate.

Figure 4. (A) Raman spectra of bulk- $\mathrm{MoS}_{2} \mathrm{MoS}_{2} / p$-(F) $\mathrm{Ph}, \mathrm{MoS}_{2} / p$-(Cl) $\mathrm{Ph}, \mathrm{MoS}_{2} / p$ - $(\mathrm{Br}) \mathrm{Ph}$, and $\mathrm{MoS}_{2} / p$ - $\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$ at 633 nm ; (B) TGA profiles of bulk- $\mathrm{MoS}_{2}, \mathrm{NaK}-\mathrm{MoS}_{2}, \mathrm{MoS}_{2} / p-(\mathrm{F}) \mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Cl}) \mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Br}) \mathrm{Ph}$ and $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$ from 100 to $650{ }^{\circ} \mathrm{C}$ under air; core level spectra of (C) F 1s, (D) Cl 2 p (E) Br 3d and (F) N 1s for $\mathrm{MoS}_{2} / p-(\mathrm{F}) \mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Cl}) \mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Br}) \mathrm{Ph}$ and $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$.

The SERS mechanism can thus be explained by the excitation of a molecular resonance coupled with electron transfer from the Fermi level of the substrate into the molecule. As the Fermi level $E_{\mathrm{F}}$ of $\mathrm{NaK}-\mathrm{MoS}_{2}\left(E_{\mathrm{F}}=-5.0 \mathrm{eV}\right)$ lies energetically above the HOMO of both dyes ( $E_{\mathrm{HOMO}}, \mathrm{CV}=$ -6.0 eV and $E_{\text {Номо }}$, R6G $=-5.7 \mathrm{eV}$ ), ${ }^{17}$ the subsequent CT
from $E_{\mathrm{F}}$ to the HOMO does not require extra energy and thus is strongly favored. This eventually results in a greatly enhanced electron transition probability, leading to high signal intensities for R6G and CV at 532 nm . At 633 nm excitation, a preresonance condition originates strong CV intensities, whereas no R6G signal can be measured because it is off-
resonance with the molecular excitation. The absence of electronically excited states in both dye molecules at 785 nm and the consequently missing SERS signals are in line with this interpretation (Figure S6). Further, the extraordinarily large enhancement of the vibrational out-of-plane modes at 611 and $775 \mathrm{~cm}^{-1}$ in R6G and the mode at $914 \mathrm{~cm}^{-1}$ in CV, compared to the in-plane modes, are related to vibrionic coupling between a molecular resonance and CT state. ${ }^{47,48}$

The reproducibility and signal homogeneity are also important parameters for SERS substrates in routine analytical applications. The homogeneity of the SERS signals for R6G at $611 \mathrm{~cm}^{-1}$ and CV at $1620 \mathrm{~cm}^{-1}$ on $\mathrm{NaK}-\mathrm{MoS}_{2}$ was studied by Raman mapping (Figures $\mathrm{S} 7-\mathrm{S} 9$ ). To evaluate the reproducibility for R6G and CV, we randomly collected SERS spectra from 20 different positions on the same $\mathrm{NaK}-\mathrm{MoS}_{2}$ substrate (Figures S8 and S9). The results indicate uniform and reproducible SERS signals over the whole surface, which is likely related to homogenous and efficient capture of the probe molecules.

Chemical Modification. In addition, chemical exfoliation by intercalation of metal ions is highly versatile because it allows carrying out chemical modifications on the exfoliated $\mathrm{MoS}_{2}$ structure. ${ }^{7}$ The chemical modification of 2D-based materials is of high interest, as it allows modifying chemical and physical properties such as conductivity, stability, and reactivity. ${ }^{49,50}$

In general, the functionalization of $\mathrm{MoS}_{2}$ is typically achieved by exploiting sulfur vacancies or defects occurring on the surface during chemical exfoliation. Recently, Pérez et al. reported a versatile mild covalent functionalization at basal planes of exfoliated $2 \mathrm{H}-\mathrm{MoS}_{2}$ and $\mathrm{WS}_{2}$ through the nucleophilic attack of sulfur atoms from the metal transition dichalcogenide structure on maleimide derivatives. ${ }^{51} \mathrm{M}$. Pumera et al. reported a highly efficient modification of $\mathrm{MoS}_{2}$ in water with thiobarbituric acid by nucleophilic attack of its sulfur on the exfoliated $\mathrm{MoS}_{2}$ material. ${ }^{52}$ 1T- $\mathrm{MoS}_{2}$ presents a higher chemical reactivity toward functionalization, especially at basal sites, as compared to $2 \mathrm{H}-\mathrm{MoS}_{2}{ }^{53}$ Voiry et al. successfully functionalized the surface of $1 \mathrm{~T}-\mathrm{MoS}_{2}$ via the covalent attachment of organohalide functional groups. ${ }^{25}$ Chemically exfoliated $\mathrm{MoS}_{2}$ can also be covalently functionalized by aryl diazonium compounds. Knirsch et al. and Benson et al. reported a well-known chemical approach, which does not rely on structural defects, to functionalize the surface of chemically exfoliated $1 \mathrm{~T}-\mathrm{MoS}_{2}$ with substituted phenyl diazonium salts. ${ }^{24,34}$ Thus, the negatively charged 1 T phase $\mathrm{MoS}_{2}$ nanolayers obtained by treatment with NaK alloy were functionalized with different para ( p )-substituted aryl diazonium salts, thereby demonstrating the versatility of the proposed reaction on the $\mathrm{MoS}_{2}$ surface. For this purpose, we selected four para-substituted ( $\mathrm{R}: \mathrm{F}, \mathrm{Cl}, \mathrm{Br}$, and $\mathrm{NO}_{2}$ ) aryl diazonium salts with heteroatoms because they can be readily analyzed by XPS. We refer to $\mathrm{MoS}_{2}$ functionalized with para F , $\mathrm{Cl}, \mathrm{Br}$, or $\mathrm{NO}_{2}$-phenyl rings as $\mathrm{MoS}_{2} / p$-( F$) \mathrm{Ph}, \mathrm{MoS}_{2} / p$ (Cl) $\mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Br}) \mathrm{Ph}$, or $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$, respectively. It is worth mentioning that, in principle, substituents of phenyl groups would not be reduced by the NaK alloy during the reaction because the same amount of diazonium compounds and NaK alloy were used, and the diazonium group is more readily reduced. ${ }^{34,53}$

Chemically functionalized $\mathrm{MoS}_{2}$ derivatives were characterized by Raman spectroscopy, XPS, FTIR, TGA, and TEM. In Raman spectroscopy, all functionalized $\mathrm{MoS}_{2}$ samples were
found to display the expected transitions around at $376 \mathrm{~cm}^{-1}$ $\left(\mathrm{E}_{2 \mathrm{~g}}\right)$ and $402 \mathrm{~cm}^{-1}\left(\mathrm{~A}_{1 \mathrm{~g}}\right)$ and also to have weak Raman peaks for $\mathrm{J}_{1}, \mathrm{~J}_{2}$, and $\mathrm{J}_{3}$ modes, indicating the presence of the 1 T phase after functionalization (Figure 4A). ${ }^{34}$ The covalent functionalization of $\mathrm{MoS}_{2}$ layers was also confirmed by FTIR (Figure S14). All functionalized samples showed the characteristic $\mathrm{C}=$ C stretching bands of benzene rings located around $1640 \mathrm{~cm}^{-1}$ and the weak $C-S$ stretching bands between 620 and 690 $\mathrm{cm}^{-1}$, suggesting that the benzene moieties were covalently attached to the $\mathrm{MoS}_{2}$ surface via $\mathrm{C}-\mathrm{S}$ bonds. Additionally, $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$ presented two main bands at 1504 and $1330 \mathrm{~cm}^{-1}$, which were attributed to characteristic asymmetric and symmetric stretching of a nitro group attached to the phenyl moiety.

The thermal properties and FD of chemically exfoliated and derivative $\mathrm{MoS}_{2}$ samples were investigated by TGA in air. Figure 4 B shows that $2 \mathrm{H}-\mathrm{MoS}_{2}$ started to lose weight at approximately $350{ }^{\circ} \mathrm{C}$, which is attributed to partial oxidation of $\mathrm{MoS}_{2}$ into $\mathrm{MoO}_{3}$. In addition, the surface functional groups were decomposed in the range of $200-500{ }^{\circ} \mathrm{C}$, as expected (Table 3). The second rapid weight loss ( $>50 \% \mathrm{wt}$ ) in all

Table 3. FD of 1T-MoS 2 Nanosheets Obtained by TGA

| functional group | weight loss $(\%)^{a}$ | $\mathrm{FD}^{b}$ |
| :---: | :---: | :---: |
| $p-\mathrm{NO}_{2}-\mathrm{C}_{6} \mathrm{H}_{4}$ | 11.5 | 5.9 |
| $p-\mathrm{F}^{b}-\mathrm{C}_{6} \mathrm{H}_{4}$ | 6.5 | 8.6 |
| $p-\mathrm{Cl}-\mathrm{C}_{6} \mathrm{H}_{4}$ | 5.6 | 9.1 |
| $p-\mathrm{Br}-\mathrm{C}_{6} \mathrm{H}_{4}$ | 7.2 | 16.5 |

${ }^{a}$ Determined weight loss at $650{ }^{\circ} \mathrm{C} .{ }^{b}$ Number of $\mathrm{MoS}_{2}$ molecules per functional group
samples was attributed to the decomposition of $\mathrm{MoS}_{2}$ by sublimation of $\mathrm{MoO}_{3}$ (Figure S16). ${ }^{54,55}$ The FD for all functionalized samples was calculated by considering the decomposition of $\mathrm{MoS}_{2}$ at $650{ }^{\circ} \mathrm{C}$, according to eq 1 .

The results suggest that the reactivity of the diazonium compounds is related to the substituted groups in the phenyl ring ( $\mathrm{Br}<\mathrm{Cl}<\mathrm{F}<\mathrm{NO}_{2}$ ). This trend can be explained by the single-electron transfer reaction mechanism from negatively charged $\mathrm{MoS}_{2}$ to the diazonium compound, being reduced to the corresponding aryl radical. ${ }^{44}$ The lower reduction potentials of the employed diazonium salts are caused by the stronger electron-withdrawing substituted groups in the phenyl ring ( $\mathrm{Br}<\mathrm{Cl}<\mathrm{F}<\mathrm{NO}_{2}$ ), improving the electron transfer process, which is in agreement with previous results for carbon nanotubes. ${ }^{56}$

The XPS analysis was used to study the atomic composition of $\mathrm{MoS}_{2}$ surfaces (Figures S17-S22). XPS was first employed to provide evidence for the functionalization of $\mathrm{MoS}_{2}$ derivatives, by identifying and quantifying the functional groups anchored to the surface (Table S2). Bulk- $\mathrm{MoS}_{2}$ is not expected to contain C and O in the bulk material; however, the undesired C and O content probably arises from CO and $\mathrm{CO}_{2}$ species in air, adsorbed on the substrates. Such $C$ and $O$ contents were detected by XPS in the starting material and in the rest of functionalized $\mathrm{MoS}_{2}$ samples, with the same proportion. The presence of $\mathrm{F}, \mathrm{Cl}, \mathrm{Br}$, and N was detected after chemical modification in the atomic composition of $\mathrm{MoS}_{2} / p$ (F) Ph (1.0\%), $\mathrm{MoS}_{2} / p-(\mathrm{Cl}) \mathrm{Ph}(0.9 \%), \mathrm{MoS}_{2} / p-(\mathrm{Br}) \mathrm{Ph}$ (0.7\%), and $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right) \mathrm{Ph}$ (3.8\%), respectively. Besides, the deconvolution of $\mathrm{F} 1 \mathrm{~s}, \mathrm{Cl} 2 \mathrm{p}, \mathrm{Br} 3 \mathrm{~d}$, and N 1 s for $\mathrm{MoS}_{2} / p$ (F) $\mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Cl}) \mathrm{Ph}, \mathrm{MoS}_{2} / p-(\mathrm{Br}) \mathrm{Ph}$, and $\mathrm{MoS}_{2} / p-\left(\mathrm{NO}_{2}\right)-$

Ph , respectively, showed spectral components from $\mathrm{C}-\mathrm{F}$ (687.4 eV), $\mathrm{C}-\mathrm{Cl}(200.9 \mathrm{eV}), \mathrm{C}-\mathrm{Br}(71.0 \mathrm{eV})$, and $\mathrm{C}-\mathrm{NO}_{2}$ ( 399.8 and 405.6 eV , Figure $4 \mathrm{C}-\mathrm{F}$ ). The presence of these chemical bonds on the corresponding $\mathrm{MoS}_{2}$ surfaces confirmed functionalization. The obtained XPS results are in agreement with related functionalization approaches in the literature, ${ }^{24,25,34,53}$ confirming the presence of $p$-substituted benzene functional groups on $\mathrm{MoS}_{2}$ layers. TEM images indicate that functionalized $\mathrm{MoS}_{2}$ derivatives keep dimensions similar to those of exfoliated material after chemical modification (Figures S24C-F). The elemental analysis of the different modified $\mathrm{MoS}_{2}$ derivatives was performed to calculate the FD with respect to the $\mathrm{C} / \mathrm{S}$ atom ratio (Table S 3 ). The $\mathrm{C} / \mathrm{S}$ ratios of functionalized materials were higher than those for NaK$\mathrm{MoS}_{2}$ because of the introduction of phenyl groups on the $\mathrm{MoS}_{2}$ surfaces.

## CONCLUSIONS

In conclusion, we report a novel approach for exfoliation and covalent functionalization of $\mathrm{MoS}_{2}$, which provides a remarkably efficient phase modification, by using NaK alloys. The proposed exfoliation method leads to highly enriched 1 T phase $\mathrm{MoS}_{2}$ ( $94.5 \%$ ). $\mathrm{MoS}_{2}$ was chemically functionalized by radical reactions with different phenyl diazonium compounds, leading to $\mathrm{MoS}_{2}$ enriched in metallic 1 T phase. $\mathrm{NaK}-\mathrm{MoS}_{2}$ revealed a remarkable SERS enhancement on R6G and CV, because of an efficient CE mechanism, which may open the way toward further sensing applications. Work is in progress to explore the limits of this approach, in terms of reactivity, physical properties of the obtained enriched 1T phase $\mathrm{MoS}_{2}$ materials (e.g., electrical conductivity, optical properties, etc.), and sensing applications.
