ABSTRACT

Context. The recent *Gaia* Data Release 3 has revealed a catalogue of more than eight hundred thousand binary systems. The release provides orbital solutions for half of the systems, with the majority of them being unresolved astrometric binaries. However, some astrophysical parameters are still unknown for most of them, such as the spectral type and the mass of each companion, since they can only be derived from the relative orbit and spectroscopic data.

Aims. The purpose of this work is to develop a methodology that would allow us to obtain those fundamental stellar parameters, along with those related to the geometry and the ephemeris of the system, to find out whether it can be optically resolved.

Methods. To obtain precise values for each component, we proposed an analytic algorithm to estimate the only two possible relative orbits and pairs of masses of main sequence (MS) astrometric binaries using all the available astrometric, photometric, and spectroscopic data from *Gaia* DR3. In some cases, it is possible to select the solution that is more aligned with the rest of the data.

Results. We deduced two possible values for the individual absolute magnitudes, masses, and effective temperatures for each binary, as well as the size of the telescope necessary to resolve their components. We present the workflow of our algorithm applied to the Ephemeris, Stellar Masses, and relative ORbits from GAia (ESMORGA) catalogue, along with the individual masses, absolute magnitudes, and effective temperatures derived for 49 530 binaries.

Key words. methods: data analysis – methods: numerical – astrometry – binaries: general

1. Introduction

Since the orbital motion of binary stars was discovered more than 200 yr ago (Herschel 1803), the study of stellar systems has become a key topic in astronomy. The scope of binary research extends to several areas, including stellar dynamics, stellar evolution, exoplanetology, and galaxy mapping, since the determination of the individual masses of the system from calculated binary orbits allows for its evolution to be studied. In addition, binary orbits provide a good distance estimation tool, namely, the dynamical parallax (Heintz 1978).

The observational techniques that allow the greatest numbers of orbits to be calculated are speckle interferometry (Labeyrrie 1970; Balega & Tikhonov 1977; McAlister 1983), adaptive optics (Babcock 1953), and space surveys (Perryman et al. 1997; *Gaia* Collaboration 2023). In this work, we focus on the latest data release of the *Gaia* mission: *Gaia* DR3.

The high accuracy of the positions and proper motions afforded by *Gaia* has allowed for detections of an unprecedented 338 215 astrometric binary stars, with orbital solutions for 145 259 of them to date. However, since the astrometric orbit shows the movement of the photocentre of the system

around its centre of mass (rather than the orbital motion of one component around the other), the *Gaia* table of binary masses (`gaiadr3.binary_masses`) only includes estimates \hat{M}_A and \hat{M}_B of the individual masses of main sequence (MS) components if a spectroscopic orbit is also available (as it occurs for 33 467 `AstroSpectroSB1` solutions; hereafter noted as: astrospectroscopic solutions). For the 111 792 binaries with only pure astrometric orbits, the \hat{M}_A is given, but for the secondary only an estimated interval, $[\hat{M}_B^{\min}, \hat{M}_B^{\max}]$, has been provided (*Gaia* Collaboration 2023). Shahaf et al. (2019) proposed an alternative procedure that allows for the primary mass – and thereby two possible mass ratios – to be obtained; however, as the authors indicated, this method ignores the contribution of the secondary component to the photometry of the system.

In this paper, we describe an algorithm that takes into account the photometric contribution of the secondary component of a system, which allows it to yield up to two possible solutions for the individual masses (demonstrating that, in fact, no more than two are possible) when sufficiently good data are supplied. Then, we used additional data from *Gaia* to achieve the most consonant solution for the individual masses. Finally, the ephemeris of the apparent orbit were obtained, so we could also assess the possibility of resolving the binary. The manuscript is organised as follows. In Sect. 2, we present our methodology, from the theoretical framework to the step-by-step description of

[★] Catalog is available at the CDS via anonymous ftp to [cdsarc.cds.unistra.fr](ftp://cdsarc.cds.unistra.fr) (130.79.128.5) or via <https://cdsarc.cds.unistra.fr/viz-bin/cat/J/A+A/682/A12>

the algorithm. The key results obtained by applying the method to *Gaia* data are shown and discussed in Sect. 3. Finally, our main conclusions are given in Sect. 4.

2. Methodology

2.1. Theoretical framework

As noted above, the orbital solutions given by the *Gaia* DR3 Non-Single Star (NSS) astrometric solution table correspond to the movement of the photocentre around the centre of mass. That orbit is related to the relative orbit via

$$\alpha = a''(f - \beta), \quad (1)$$

where α is the semi-major axis of the photocentric orbit, a'' is that of the relative orbit, and f is the mass ratio:

$$f = M_B / (M_A + M_B), \quad (2)$$

while β is the corresponding flux ratio, defined by

$$\beta = f_{G,B} / (f_{G,A} + f_{G,B}) = 1 / (1 + 10^{0.4\Delta m_G}), \quad (3)$$

where $f_{G,A}$ and $f_{G,B}$ are the spectral flux densities in the *Gaia* *G*-band of both components, and Δm_G is their magnitude difference. Therefore, starting with the α given by the *Gaia* NSS table, we can calculate a'' if we know the individual masses, M_A and M_B , of both companions, as well as their Δm_G . Unfortunately, those three mentioned variables are a priori unknown (in truth, they are among the unknowns that we want to solve). We can use the calibration of Pecaut & Mamajek (2013) for MS stars to obtain the stellar mass from its absolute magnitude or colour. However, it is very often the case that the absolute magnitude of each component is not determined, only the combination of light of both components, known as the combined absolute magnitude, M_G .

Inspired by Edwards (1976) and Campo (2019), we performed a decomposition of the overall photometry of the system by expressing M_G as an interpolation of the individual magnitudes, $M_{G,A}$ and $M_{G,B}$, weighted by Δm_G :

$$M_{G,A} = M_G + 2.5 \log \left(1 + 10^{-0.4\Delta m_G} \right), \quad (4)$$

with $M_{G,B} = M_{G,A} + \Delta m_G$. We still need to know Δm_G to work but now we have it as an input parameter in both Eqs. (1) and (4), so that we can take advantage of that to develop an analytical and recursive algorithm (see Sect. 2.2) to get the set of possible solutions for Δm_G and, thus, the rest of the output parameters.

2.2. Algorithm: Step by step

The algorithm described here is used to obtain a set of candidates for the relative semi-major axis, a'' from the semi-major axis of an astrometric orbit, α . During the process, each solution yields a value for the Δm_G of the unresolved system along with a precise estimate of the individual mass of each component.

Furthermore, we can compute the orbital ephemeris so we can derive straightforwardly the minimum ρ''_{\min} and maximum ρ''_{\max} angular separation between their components. Subsequently, and together with Δm_G , the minimum size that a telescope needs to resolve that system comes to light.

2.2.1. Sample selection and preprocessing

Given an NSS astrometric or astrospectroscopic solution from *Gaia* DR3, we first have to determine whether its composite spectrum corresponds to an MS star, since the calibrations we will use are only valid for stars with spectral types between B1.5V and L2V. The luminosity class of the input star can be determined using the logarithm of its surface gravity, $\log g$, given in the *Gaia* DR3 source catalogue as `logg_gspphot` (in dex). For instance, on the basis of the work of Angelov (1996), Zboril et al. (1997) and Bastien et al. (2016), we could restrict the input MS stars to those with $\log g \geq 4.0$ dex. However, the surface gravity of an unresolved binary considered as a single star is not very reliable, as the cooler companion gives rise to underestimation of the effective temperature, and, thus, also of $\log g$, which is highly correlated with T_{eff} and metallicity (El-badry et al. 2018; Ting et al. 2017). Therefore, instead of using the surface gravity computed by GSP-Phot on the basis of a single-star model, we redefine $\log g$ as the lesser of the Multiple Star Classifier (MSC) individual surface gravities, `logg1_msc` and `logg2_msc`, assuming that both components are at the same evolutionary stage and that their flux ratio is smaller than 5. This is the value of $\log g$ used to exclude stars that are not on the MS.

Next, the seven Campbell orbital elements for the astrometric orbit were derived together with their uncertainties, as fully detailed in Halbwegs et al. (2023). Thereafter, we applied the same filter used in *Gaia* Collaboration (2023) for discarding low signal-to-noise ratio (S/N) solutions, by imposing $S/N > 5$ for α and $S/N > 2$ for $\sin I$ in astrometric orbits, while $\log_{10}(S/N) > 3.7 - 1.1 \log_{10} P$ is also required for `OrbitalAlternative` solutions. Moreover, $S/N > 5$ for $\sqrt{C_1^2 + H_1^2}$ and a_1 in the astrospectroscopic ones is demanded. Next, we go on to describe how the algorithm works, step by step, below.

2.2.2. First step: Photometric decomposition

For each binary, we get its combined absolute magnitude (M_G) from the *G*-band mean apparent magnitude, m_G , given by *Gaia* DR3 as `phot_g_mean_mag` (mag): after m_G is first corrected for interstellar absorption and scattering by subtracting the extinction in the *G*-band (available as `ag_msc` (mag)), M_G is obtained from the distance-modulus relation using `parallax` (mas). The initial values for $M_{G,A}$ and $M_{G,B}$ are then obtained by choosing a small enough magnitude difference, e.g. $\Delta m_G = 0.05$ mag, and using Eq. (4).

2.2.3. Second step: Initial solution

Subsequently, the method uses the calibration of Pecaut & Mamajek (2013) to compute the individual masses, M_A and M_B , by means of a cubic spline interpolation. At the same time, we can use the later Δm_G to calculate the flux ratio, β , by means of the second equality in Eq. (3). Moreover, the mass ratio f is computed from Eq. (2) together with the individual masses, M_A and M_B , estimated in the first step. Therefore, we can obtain an initial value for a'' that, like α , is measured in arc seconds. This is not a problem because we have the *Gaia* parallax, $\bar{\omega}$, so that the value of a in au is recovered.

2.2.4. Third step: Again and again

From the value of a derived in the previous step in addition to the orbital period, P , available in the *Gaia* DR3 NSS astrometric

solution, by means of Kepler's third law, we can determine, the sum of the masses (in this case, referred to as 'Keplerian masses', to differentiate them from those obtained with the calibrations), $\mathcal{M}_T^{\text{kep}} = \mathcal{M}_A^{\text{kep}} + \mathcal{M}_B^{\text{kep}}$. On the other hand, by adding up the initial masses, we get $\mathcal{M}_T = \mathcal{M}_A + \mathcal{M}_B$; it is clear that if the assumed value for Δm_G is correct, then $\mathcal{M}_T^{\text{kep}} = \mathcal{M}_T$.

For that reason, the core idea of the algorithm is to perform the previous set of calculations with different values of Δm_G , until the above equality is verified. Therefore, the algorithm repeat the previous steps increasing Δm_G by 0.05 mag and, by doing this recursively and performing the following multiplication for each i iteration,

$$(\mathcal{M}_{T_i} - \mathcal{M}_{T_i}^{\text{kep}}) (\mathcal{M}_{T_{i-1}} - \mathcal{M}_{T_{i-1}}^{\text{kep}}); \quad (5)$$

it is clear that if it changes its sign then the solution is located in the interval $[\Delta m_{G,i-1}, \Delta m_{G,i}]$ (see Sect. 3.1 for further details). Thus, the process continues until an arbitrarily high Δm_G , e.g. $\Delta m_G = 10$ mag, since there can be more than a possible solution. Subsequently, we consider the medium point of each solution interval as an estimator of the Δm_G solution.

2.2.5. Fourth step: Ephemeris calculation

Using the obtained solutions for Δm_G and the mean value of the individual masses (corresponding to the extremes of the interval in which we found the solution) we get, through Kepler's third law, the relative semi-major axis, a .

From this – and together with the rest of the orbital parameters derived from the Innes constants – we are able to compute the apparent orbit through the widely known ephemeris algorithm (see e.g. Abushattal et al. 2020). Ultimately, the minimum (ρ_{\min}) and maximum (ρ_{\max}) angular separations between the components are derived, as well as their corresponding dates.

2.3. Evaluating consonance with Gaia DR3

For binaries with pure astrometric orbits in *Gaia* DR3 we quantify consonance with our possible solutions by assigning to each of the latter a grade defined in terms of the relative difference between \mathcal{M}_A and $\hat{\mathcal{M}}_A$, $\delta_{\mathcal{M}_A} = |\mathcal{M}_A - \hat{\mathcal{M}}_A| / \hat{\mathcal{M}}_A$, as follows:

$grade = 1$, if $\delta_{\mathcal{M}_A} \leq 0.1$,
 $grade = 2$, if $0.1 < \delta_{\mathcal{M}_A} \leq 0.2$,
 $grade = 3$, if $0.2 < \delta_{\mathcal{M}_A} \leq 0.3$,
 $grade = 4$, if $0.3 < \delta_{\mathcal{M}_A} \leq 0.4$,
 $grade = 5$, if $0.4 < \delta_{\mathcal{M}_A} \leq 0.5$, and so on.

These grades are listed in the catalogue ESMORGA (see Sect. 3.3). The more consonant of our two possible solutions is identified as that with \mathcal{M}_A closer to $\hat{\mathcal{M}}_A$, so long as $\mathcal{M}_B^i \in [\hat{\mathcal{M}}_B^{\min}, \hat{\mathcal{M}}_B^{\max}]$.

For binaries with astrospectroscopic orbits in *Gaia* DR3, we assign grades in the same way as above, but using, instead of $\delta_{\mathcal{M}_A}$, the greater of $\delta_{\mathcal{M}_A}$ and $\delta_{\mathcal{M}_B}$, which is analogously defined. For these binaries, consonance with *Gaia* DR3 can also be examined in terms of the binary mass function (f_m , in \mathcal{M}_\odot), which (like the total mass) can be calculated by two routes: firstly, from the Innes constants C_1 and H_1 provided by *Gaia* DR3 for astrospectroscopic solutions (Gaia Collaboration 2023):

$$f_m = (C_1^2 + H_1^2)^{3/2} P^{-2}, \quad (6)$$

where C_1 and H_1 are in au and P in years; and secondly, from the individual masses as

$$\hat{f}_m = \frac{\mathcal{M}_B^3 \sin^3 I}{(\mathcal{M}_A + \mathcal{M}_B)^2}. \quad (7)$$

We consider that our solution passes this test of consonance if

$$|f_m - \hat{f}_m| / f_m \leq 0.5. \quad (8)$$

This binary mass function test can also be applied to binaries with only pure astrometric orbits in *Gaia* DR3, using for f_m the estimate used by Tanikawa et al. (2023):

$$f_m = 3.7931 \times 10^{-5} K_1^3 P (1 - e^2)^{3/2}, \quad (9)$$

where K_1 is the RV semi-amplitude of the primary component, approximated as half `rv_amplitude_robust`. However, this parameter corresponds to RV variability and not to a fitted RV curve, so caution is needed, especially for eccentric orbits.

2.4. Error propagation

Finally, to estimate the propagation of uncertainties σ , we have used the standard Taylor-expansion method to obtain σ_{M_G} , assuming $\sigma_{m_G} = 0.010$ mag and $\sigma_{\Delta m_G} = 0.025$ mag. Subsequently, to estimate the error in the non-linear interpolations, we performed 10 000 Monte Carlo simulations assuming normally distributed M_G errors ($\sim \mathcal{N}(M_G, \sigma_{M_G})$). Taking the mean and standard deviation of the interpolated samples of masses and effective temperatures as the estimates and their uncertainties, respectively, we followed the subsequent propagation of the uncertainty through to the ephemeris by means of partial derivatives.

3. Results and discussion

3.1. Examining the numerical convergence

The process is equivalent to find the zeros of the function:

$$\Delta \mathcal{M}(\Delta m_G) = \mathcal{M}_T(\Delta m_G) - \mathcal{M}_T^{\text{kep}}(\Delta m_G). \quad (10)$$

To study how $\Delta \mathcal{M}(\Delta m_G)$ behaves as we scan through a range of Δm_G values, we ran the algorithm on 796 *Gaia* DR3 astrometric binaries with well-established combined magnitudes available at SIMBAD¹, computing $\Delta \mathcal{M}$ for $\Delta m_G \in [0.5, 8]$ mag with increments of 0.05 mag.

As can be seen in Fig. 1, the function $\Delta \mathcal{M}$ shows an asymmetric parabolic shape that, depending on the star, cut the abscissa axis in different points. The black and green quasi-parabolas show two and one zeros (but maybe one more could be found if we increase the superior limit of Δm_G). There is a straightforward mathematical explanation for this: β decreases by a factor of $\sim 10^{-0.4 \Delta m_G}$, whereas f comes from the quotient of two polynomials of degree 3 (the cubic spline interpolations), so that β will decrease faster at the beginning and therefore α/a'' has a maximum. In Fig. 2, we show this behaviour for a generic *Gaia* DR3 MS binary. Then, for the same scale factor there are generally two feasible values for Δm_G .

Regarding the no-solution case, corresponding to the blue quasi-parabola that does not touch the abscissa axis, it should be recalled that even though we are evaluating $\Delta \mathcal{M}$ as a function of

¹ <http://simbad.u-strasbg.fr/simbad>

Fig. 1. Graphical representation of ΔM for three *Gaia* DR3 unresolved astrometric binaries, with two solutions (black), a single solution (green), and zero solutions (blue) for Δm_G .

Fig. 2. Plot of f , β , and α/a'' versus Δm_G for *Gaia* DR3 5706079252076583424.

Δm_G , its values also depend on the dynamical ($\alpha, \bar{\omega}, P$) properties of the astrometric binary. Therefore, at one extreme of the spectrum of possibilities, this might be entirely due to the *Gaia* DR3 photocentre orbit being erroneous; at the other, this could be due to an inappropriate use of the Pecaut–Mamajek calibration, namely, erroneous assumptions as regards the luminosity class of the components.

3.2. Validation of the algorithm

To test the algorithm we have cross-matched the *Gaia*'s sources with an astrometric solution with those contained in the Sixth Catalog of Orbits of Visual Binary Stars (WDS-ORB6), using a search radius of $5''$. By doing so, we have constrained a set of 26 *Gaia* astrometric orbits with a resolved orbit in the WDS-ORB6. Then, we have selected those belonging to the MS, attending to *SIMBAD* and/or to the $\log(g)$, and filtering them by means of the 10σ -criteria used in Chevalier et al. (2023) to discard different orbits within the same multiple system.

The comparison on the resulting 10 semi-major axes is shown in Table 1. By using the similarity criteria with \hat{M}_A and \hat{M}_B , or the f_m to constrain the most consonant solution (see

bold rows in Table 1), the relative discrepancy is 7–10%, respectively. The problem arises when comparing the Δm_G obtained by our algorithm with that of the ORB6. For each pair of solutions, there is one that is close to the ORB6 Δm_V , whereas for WDS 09275-5806, 18040+0150, and 12114-1647, neither the *Gaia* masses nor f_m selecting criteria seem to work. This holds true whether we calculate the f_m with `rv_amplitude_robust` or with C_1 and H_1 (for *AstroSpectroSB1* solutions), in which case the binary mass function calculation is especially strong. Therefore, if we accept the ground-based measurements as benchmarks, the *Gaia* data used to compute those SB1 orbits and masses may benefit from some revision.

3.3. Application on the *Gaia* DR3 astrometric orbits: ESMORGA catalogue

By means of the criteria described in Sect. 2.2.1, we selected an initial sample of 82 759 astrometric binaries. By applying the algorithm to all of them, with $\Delta m_G \in [0.05, 20]$ mag in steps of 0.05 mag, we obtained solutions for a total of 52 678 systems. Subsequently, this set was reduced to 49 530 by choosing only those with individual masses and binary mass functions in consonance with the *Gaia* values. Finally, we have included these latter in the catalogue ESMORGA (Ephemeris, Stellar Masses and relative ORbits from *GAia*), which can be downloaded from the Ramón María Aller Astronomical Observatory website². The full table will be made available on VizieR. Here, we present a description of the catalogue, column by column.

3.3.1. Description of the catalogue

Each binary corresponds to a row, while the uncertainties are shown in the row below. If two possible solutions for the binary are provided, they appear in consecutive rows. The columns with the parameters per source are organised as indicated in Table 2.

3.3.2. Catalogue statistics

The catalogue provides just a single solution for 10 643 binaries, 21.5% of the total, and 39 639 binaries are marked as grade 1. Several binary parameters can be thus studied, being the separations between the astrometric companions the most straightforward one. In Fig. 3, the density histogram of the semi-major axes in au is shown in red. The sample reaches the 99th percentile to enhance data visualization. As can be seen, *Gaia* astrometric binaries are very close, with separations within the Solar System scale, most of them having a semi-major axis between 0.5 and 2 au. Moreover, there is a deep decay around 1 au that, by comparison with the histogram of the periods (blue), shows to be associated with the *Gaia*'s observational bias for binary orbits of 1 yr, which is due to the coupling of the orbital and parallactic motions (Gaia Collaboration 2023).

In the case of astrospectroscopic orbits, a_1 is straightforwardly obtained and, by means of the following relation,

$$\frac{a}{M_A + M_B} = \frac{a_1}{M_B} = \frac{a_2}{M_A}, \quad (11)$$

the semi-major axis of the secondary component around the centre of mass, $a_2 = a_1 M_A / M_B$, is known. Then, we can derive an alternative semi-major axis $\hat{a} = a_1 + a_2$ and, from it, another

for the parallax $\hat{\omega} = a''/\hat{a}$ (hereafter, the astrospectroscopic parallax).

It is clear that, if the relative orbit aligns with the *Gaia* spectroscopic one, then $\bar{\omega} \approx \hat{\omega}$. Indeed, from the comparison of the 3714 single-solution astrospectroscopic parallaxes of grade ‘1*’ and ‘2*’ with those of *Gaia*, there is a mean absolute discrepancy of 0.8 mas (std = 2.6 mas) for grade ‘1*’, and 1.9 mas (std = 3.2 mas) for grade ‘2*’. This may be considered as an additional validation for astrospectroscopic solutions.

Finally, we present a histogram in Fig. 4 displaying the masses of primary and secondary components up to the 99.9th percentile, although the maximum mass obtained was $2.76 M_\odot$ for a primary and $1.78 M_\odot$ for a secondary, while the minimum

masses correspond to a primary of $0.09 M_\odot$ and a secondary of $0.08 M_\odot$.

3.4. Example of use in resolving an unresolved astrometric binary

As commented in Sect. 2.2.5, the algorithm allows to draw the apparent orbit of the secondary companion around the primary for any unresolved astrometric binary, as can be seen in Fig. 5. In this case, $\Delta m_G = 0.78$ mag, $\rho_{\min} = 30.4 \pm 0.3$ mas in 2024.36, and $\rho_{\max} = 69.1 \pm 0.4$ mas in 2024.88. Accordingly, a telescope of between 4 and 1.8 m would be required, respectively, to resolve it, depending on the observation date (see e.g. Tokovinin et al. 2022).

4. Conclusions

We have developed and implemented a novel algorithm to calculate the only two possible semi-major axes for the relative orbit of MS unresolved astrometric binaries. A unique solution can be obtained if additional spectroscopic data such as an SB1 orbit or a reliable RV amplitude is available. Through our procedure, based on the decomposition of the combined photometry, we are able to determine precise values for decisive astrophysical parameters such as the masses and effective temperatures of each component. Moreover, the ephemerides of the calculated apparent orbits of these systems provide the maximum and minimum angular separations between the components, which, in turn, can

be used to evaluate the feasibility of resolving them. The results for 49 530 binary systems using this methodology are presented in the ESMORGA catalogue.

We have validated our algorithm by comparing its results for the semi-major axis with ten orbits in the catalogue WDS-ORB6. The algorithmic semi-major axes differ, on average, by less than 10% from the ground-based ones, while for Δm_G we have found contradictory clues on that computed by the algorithm and the mass ratio of the *Gaia* binary mass table; thus, more observations over more astrometric systems must be carried out to improve on these results. On the other hand, the stellar masses computed by our methodology are in high consonance (mostly, *grade* = 1) with those calculated in *Gaia* Collaboration (2023), which validates the procedure and allows us to choose (when needed) the most plausible solution between those two provided in the first instance by the methodology. However, we recommend taking into account additional data whenever possible to choose the definitive solution.

We aim for this work to serve as a supplementary tool to exploit the enormous amount of astrometric and astrophysical data provided by *Gaia* and future astrometric missions. We expect that its application to the forthcoming *Gaia* Data Release 4 should allow us to choose the preferred solutions with more confidence, thanks to the growing number of released observations and more robust RV amplitudes.

Acknowledgements. The authors thank the referee, Andrei Tokovinin, for his valuable comments and suggestions that have served to improve the performance of the algorithm. This work presents results from the European Space Agency (ESA) space mission *Gaia*. *Gaia* data are being processed by the *Gaia* Data Processing and Analysis Consortium (DPAC). Funding for the DPAC is provided by national institutions, in particular the institutions participating in the *Gaia* Multi-Lateral Agreement (MLA). The *Gaia* mission website is <https://www.cosmos.esa.int/gaia>. The *Gaia* Archive website is <http://archives.esac.esa.int/gaia>. Another catalogues and databases that have been crucially important for the preparation of this work, are: the Washington Double Star Catalog (WDS) and the Sixth Catalog of Orbits of Visual Binary Stars (ORB6), maintained by the US Naval Observatory (USA, <https://crf.usno.navy.mil/wds>); the SIMBAD database, operated by the Centre de Données astronomiques de Strasbourg (France, <http://simbad.cds.unistra.fr/simbad/>); and the Astrophysics Data System (NASA/SAO, <https://ui.adsabs.harvard.edu/>). This paper was supported by the Spanish ‘Ministerio de Ciencia e Innovación’ under the Project PID2021-122608NB-I00 (AEI/FEDER, UE), and by the European Union under the INVESTIGO (Next Generation) grant.
